Rickettsias such as *Rickettsia rickettsii*, *Ehrlichia equi* and *Ehrlichia chaffeensis*, and *Orientia tsutsugamushi* are obligate intracellular bacterial parasites transmitted by insects or ticks. These bacteria are the etiologic agents of Rocky Mountain spotted fever, ehrlichiosis, and scrub typhus, respectively, and may theoretically be transmitted by transfusion. However, there are no reports of adverse transfusion reactions in recipients who have received blood units from rickettsia-infected donors.[53,54] Similarly, recipients of blood components from donors subsequently diagnosed as having Lyme disease, which is caused by the tick-borne spirochete *Borrelia burgdorferi*, have not demonstrated any signs or symptoms of the disease.[55–61]

SOURCES OF CONTAMINATION

Possible mechanisms of blood component contamination, listed in Table 47–1, involve the blood donor, the collection procedure, the collection pack, and the various blood processing procedures. It is recognized that in most cases the source of the bacterial contamination cannot be determined.

Donor Bacteremia

Obviously, most bacteremic people are symptomatic and would not be accepted as blood donors. In many countries, including Canada and the United States, the donor temperature must be no higher than 37.5°C. However, donors in an asymptomatic incubation period or in the recovery phase from a bacterial-associated upper respiratory tract infection or gastroenteritis have been linked to episodes of bacterial contamination.[2,9,19] In cases of transfusion-

Table 47–1 **Sources of Bacterial Contamination and Control Mechanisms**

Source of Contamination	Implicated Bacteria (Reference)	Control Measures
Transient asymptomatic donor bacteremia	*Yersinia enterocolitica*[1,7,8,40–43] *Streptococcus bovis*[48,49] *Staphylococcus aureus*[3] *Salmonella enterica*[65] *Treponema pallidum*[19]	Donor screening Pretransfusion detection
Blood collection	*Staphylococcus epidermidis, Staphylococcus aureus*[2,3,20]	Improved skin disinfection
	Clostridium perfringens[6]	Initial aliquot diversion
	Enterobacter cloacae[3,66,67] *Serratia marcescens*[66,67] *Pseudomonas fluorescens*[68]	Increased collection of apheresis platelets
Collection packs	*Serratia marcescens*[2,69–72] *Burkholderia cepacia*[73] *Enterobacter cloacae*[55]	Improved quality control
Blood processing procedures	*Burkholderia cepacia, Pseudomonas aeruginosa*[36,37,59]	Improved quality control

associated *Y. enterocolitica* septicemia reported to the U.S. Centers for Disease Control and Prevention (CDC), approximately 75% of donors recalled having diarrhea in the days preceding or following their donation.[8,43] In addition, most of these donors had high antibody titers against *Y. enterocolitica* indicating a recent infection.[2,43] Gastrointestinal symptoms were also noted retrospectively in the *Y. enterocolitica* cases in autologous donors discussed previously.[21,22,24]

Streptococcus bovis can also be transiently present in the bloodstream of asymptomatic donors who have underlying colonic problems. Investigation of a fatal transfusion-associated reaction due to platelets contaminated with this organism revealed that the donor did not present with any symptom of illness at the time of donation; however, the donor had undergone removal of a benign colonic polyp 2 months before the donation.[48] Recently, a second case of an asymptomatic donor carrying *S. bovis* in her bloodstream was reported. It was subsequently found that the woman had a colonic adenocarcinoma, which was removed without complications.[49]

A Canadian case illustrates a *S. aureus* septicemia in a patient who had been transfused with a pool of five platelet units. The donor of one of these units felt ill 3 days after his blood donation and went into septic shock with blood cultures positive for *S. aureus*. Soon after the donor's admission to the hospital, a family member informed the attending physician that he had donated blood 4 days earlier. The *S. aureus* isolates from both the donor and the recipient were found to be identical on antibiotic sensitivity testing profiles and gene mapping, indicating that they were probably from the same source. Had the blood donor not presented with a septic episode subsequent to donation, the link between the fatal septicemia and the blood transfusion would not have been made in this recipient.[3]

Similarly, donors infected with *Treponema pallidum* can be asymptomatic and have a negative nonspecific serologic test for syphilis during periods of spirochetemia. The spirochete is inactivated after several days of storage at 4°C, but rare cases of transmission have been reported with blood stored for less than 24 hours.[19]

Isolated cases of bacterial contamination also have been linked to donors with intermittent, low-grade bacteremia associated with chronic infection or transient bacteremia after dental repair.[19,51]

Blood Collection

The majority of organisms isolated from contaminated platelet components are part of the normal skin flora and are thought to enter into the venesection needle during venipuncture.[19,62] Organisms such as *Staphylococcus epidermidis*, *S. aureus*, and *Bacillus* spp. are frequent contaminants in blood culture studies. It has been postulated that, despite adequate surface disinfection, viable bacteria remain in the deeper layers of the skin, especially skin associated with a scarred phlebotomy site.[19,63] It has also been shown that *S. aureus* and *S. epidermidis* can adhere firmly to human hair despite skin disinfection.[64]

The donor's skin may also be the source of unusual pathogens. A fatal platelet transfusion reaction due to *Clostridium perfringens* was linked to a donor who had frequently changed his children's diapers.[6] Arm swab cultures from this donor revealed the presence of *C. perfringens* and other bacteria that are normal components of fecal flora, such as *E. coli* and *Enterococcus faecalis*.

A rare case of a donor who had a pet boa was linked to two transfusion-associated sepsis events in recipients of platelets contaminated with *Salmonella enterica*. The same bacterium was isolated from the recipient's blood cultures, the platelet components, and a stool sample from the boa but not from the blood donor. It is possible that the bacterium was present on the donor's skin at the time of the platelet donations.[65]

Contaminated vacuum tubes used for specimen collection after donation and nonsterile intravenous solutions used during apheresis procedures were implicated in episodes of *Serratia marcescens* and *E. cloacae* sepsis, respectively.[66,67]

Unusual practices during collection could also result in the contamination of blood products. Chaffin[68] described how a cool cloth contaminated with *Pseudomonas fluorescens*, which was placed over the sterile gauze of a donor with low pain tolerance, led to heavy contamination of an RBC unit that was transfused, causing a near-fatal transfusion reaction.

Blood Bag and Container Damage or Defect

In June 1991, six patients in Denmark and Sweden developed *S. marcescens* septicemia after transfusion of RBCs (five patients) or platelets (one patient). At least five more cases with milder symptoms were subsequently diagnosed.[69,70] All of the episodes were related to blood bags produced in a plant in Belgium. The same ribotype of *S. marcescens* was isolated from each recipient, the implicated products, 0.3% to 1.5% of blood units collected during this time period, and the dust in the factory. It was hypothesized that *S. marcescens* had contaminated the exterior of the blood bags, which were put into a clean but not sterile outer plastic package. *S. marcescens* grows well at 4°C and 22°C, even under poor nutritional conditions, and may use the plasticizer leaking out of the blood bag as a carbon source. After massive contamination of the exterior of the blood bag, the bacteria probably entered the unit at the time of blood donation, either through suction into the needle or contamination of the phlebotomist's hands and subsequently of the donor's skin.[71] In 1995, the National Blood Authority in England withdrew 7000 blood bags because of faulty seals in some of the bags.[72] At least one case of post-transfusion *Serratia* septicemia may have been caused by the faulty bags.

In 1973, a cluster of cases of *B. cepacia* was traced to low-frequency contamination of a lot of albumin vials in the United States.[73] In 1996, several cases of *E. cloacae* septicemia in the United States were related to damage to albumin vials during transport in the manufacturing facility, which resulted in cracks. This led to the recall of 10 lots of albumin and 1 lot of factor VIII by the manufacturer.[52]

Blood Processing

Contamination of plasma or cryoprecipitate on thawing in heavily contaminated water baths has been reported to lead to *B. cepacia* or *P. aeruginosa* bacteremia, endocarditis, or mediastinal wound infection.[37,38,59] Contamination can occur as a result of microscopic cracks in the bags or entry of bath water into the packs at the time of pooling. Although bacterial contamination may theoretically occur during platelet pooling, cases of sepsis associated with platelet pool

contaminations has always been traced to a constituent unit. Because of the short time frame between pooling and transfusion used in North America, the introduction of small numbers of bacteria most likely would be of little clinical consequence. However, if a sterile connecting device is used to weld tubing of platelet or RBC units before more lengthy storage, care must be taken to ensure that the connections are intact.

BACTERIOLOGIC SURVEILLANCE OF CELLULAR BLOOD PRODUCTS

Bacteriologic surveillance is part of hemovigilance in several countries. Surveillance may involve culturing of a certain number of products as part of quality assurance, culturing of platelet components as part of the routine donor testing, culturing of recipients and of the remaining blood products of all recipients who experience transfusion reactions, and reporting of such transfusion reactions to a central registry. Data obtained from studies conducted in several countries revealed that the current prevalence of bacterial contamination in platelets and RBCs is approximately 1 in 3000.[3]

In the United States, the BaCon study was conducted from 1998 to 2000 by the AABB, the American Red Cross, the CDC, and the Department of Defense. The results of this study revealed a sepsis rate of 1 in 100,000 for apheresis and whole blood–derived platelets and 1 in 5 million for RBCs. The fatality rate was 1 in 500,000 for platelets and 1 in 10 million for RBCs.[74] Because of very stringent case definitions and under-reporting, this study most likely underestimated the true frequency of septic reactions. From 2001 to 2003, 14.1% of transfusion-associated deaths reported to the FDA were due to bacterial contamination.[3]

French law requires the reporting of all transfusion reactions to the Agence Française du Sang.[75] Designated personnel in each hospital are responsible for submitting standardized reports, and the reactions are graded according to severity and possible etiology. Of the 12,058 moderate and severe reactions reported in 1996 and 1997, 405 (1.3%) were thought to be caused by bacterial contamination, as were 5 (15%) of the 33 fatal reactions for which transfusion-related causality could be clearly established. From 1994 to mid-1997, the estimated frequency of a bacteria-associated transfusion reaction was 1 in 60,000 transfused components, with 1 in 185,000 components resulting in a severe reaction and 1 in 700,000 resulting in a lethal reaction. Four reactions occurred in association with autologous RBC transfusions.[75,76] The French BACTHEM case-control study was started in 1996 to determine risk factors and sources of contamination in cases of transfusion reactions caused by bacteria.[77] This study documented a fatality rate of 1 in 140,000 due to transfusion of bacterially contaminated platelets.[78]

In the UK, the SHOT voluntary reporting system was initiated in late 1996 to compile reports of severe transfusion reactions.[79] The last SHOT report, issued in 2004, showed that from 1995 to 2003, 29 cases of bacterial infections and 7 deaths were due to the transfusion of bacterially contaminated blood products[80]; 25 platelet units and 4 RBC units were implicated in these reactions.

In Canada, 39 (11.3%) out of the 344 adverse transfusion reactions reported from April 2001 to December 2003 to The Transfusion Transmitted Injuries Surveillance System were deemed possibly due to bacterially contaminated blood products[81]; 15 units of RBCs, 18 platelet units, and 6 fresh frozen plasma units were implicated in these reactions. From 2001 to 2003, 4576 adverse transfusion reactions were reported to The Quebec Hemoviligance System[82]; 46 of these cases were deemed potentially due to bacterially contaminated blood products, although only 7 cases were confirmed (same bacterium isolated from the blood product and from blood of the recipient). Of the 7 confirmed cases, 5 involved platelets and 2 involved RBCs. One fatality was reported with one of the RBC units.

APPROACHES TO REDUCE TRANSFUSION-ASSOCIATED SEPTIC REACTIONS

Measures proposed to prevent transfusion-associated bacterial sepsis include donor screening, skin disinfection, initial aliquot diversion, and pretransfusion bacterial detection.

Donor Screening

Screening of donors to detect possible transient bacteremia is performed worldwide. Donors may be questioned about the occurrence of fevers as well as dental or medical procedures in the hours or days before donation. Retrospective questioning of donors of RBC units contaminated with *Y. enterocolitica* often reveals symptoms of gastroenteritis that occurred during the month preceding donation. However, several studies have demonstrated that the addition of questions about such symptoms would lead to unacceptable donor loss and the exclusion of many healthy blood donors.[28,83,84]

Donors who develop symptoms indicative of infection in the week after donation may be asked to notify the transfusion service. However, it has been shown that it is very likely that blood donors who develop these symptoms after donation are rarely infectious.[85] Donors may be asked about tick bites in areas where Lyme disease is endemic. However, because there have been no reported cases of Lyme disease transmission from asymptomatic donors, an AABB Advisory Group concluded that the addition of a specific question about tick bites was not necessary.[86]

Improved Skin Disinfection

Complete skin sterilization is not possible because bacteria residing in the sebaceous glands and hair follicles of the dermal connective tissue layer below the epidermis may be inaccessible to disinfectants.[2,20] Improvements in skin surface disinfection have, however, led to significantly lower blood product contamination rates. Factors affecting skin disinfection include the type and concentration of the antiseptic(s) applied, the use of single versus multiple antiseptics, one- or two-stage antiseptic application, the method of application (i.e., scrub, swab, ampule, applicator), the contact time between the antiseptic and the skin, and the expertise of the phlebotomist.[20] Data obtained from several studies suggest that superior disinfection results are associated with the use of a two-stage method, the use of a kit containing a sponge scrub followed by an ampule, and the use of tincture of iodine and alcohol instead of povidone-iodine.[20]

The AABB Technical Manual recommends the use of a two-stage method involving an initial 30-second scrub with a 0.7% iodophor solution followed by application of a 10% iodophor compound. The solution should be allowed to dry

for 30 seconds after application. In Canada, a two-stage skin disinfection method has also been implemented involving a 70% isopropyl alcohol scrub followed by the application of a 2% iodine tincture solution.[20,87] Chlorhexidine or double isopropyl alcohol is used for blood donors who give a history of allergic reactions to iodine.[2,20] In the UK, skin surface cultures after donor arm disinfection are monitored as part of quality control.[88]

Diversion of the First Aliquot of Donor Blood

Bacteria that are part of normal skin flora may be introduced into the blood bag in association with a skin core that enters the collection needle at the time of venisection.[2,19,20,62] This possibility was first proposed in 1991 by Goldman and Blajchman.[19] The removal of the first 10 to 42 mL of donor blood has been shown to significantly decrease the bacterial load in the collection bag.[2,20] Several manufacturers have developed blood collection sets with a Y configuration that permit the diversion of up to 42 mL of blood. These sets are designed so that backflow into the main bag is prevented. Samples contained in the satellite bag are then used for blood grouping and infectious disease testing.[20] Initial aliquot diversion is used for all collections in several countries, including France, the Netherlands, and Canada, but it is not mandatory in the United States.

Pretransfusion Detection

The ideal test for the detection of bacteria in blood components does not currently exist. Several methods have been designed to detect bacterial contamination in blood products, including automated bacterial culture, visual inspection of platelets before issue, monitoring of alteration in metabolic parameters during storage, direct staining for bacteria, nucleic acid amplification testing for bacterial DNA, bacterial ribosomal assays, and endotoxin or peptidoglycan detection.[26] Table 47–2 summarizes the pretransfusion detection methods that are available; they can be used either soon after blood collection or just prior to a transfusion.

Because bacteria can replicate in blood components, bacterial detection is more complex than detection of other infectious agents, whose concentration does not increase after blood collection.[89] Several factors should be considered when selecting a bacterial screening method, including timing of the test (i.e., by the blood supplier or in the hospital before transfusion), the methodology to be used for sample collection, the volume of sample needed for testing, the time required to perform the test, and whether a quarantine time is necessary for the blood product while testing is being performed.[89]

Low bacterial concentrations soon after collection require a very sensitive screening method when testing is performed by the blood supplier. Although the minimum inoculum size necessary for bacterial proliferation varies in different studies with different organisms, for many strains a very small inoculum, such as 1 colony-forming unit (CFU)/mL, may be sufficient for bacterial growth. In platelet inoculation experiments, there is usually a lag phase, followed by exponential growth, to reach a maximum concentration of 10^8 to 10^9 CFU/mL on day 2 to day 5, depending on the organism.[90] Because of bacterial proliferation during storage, less sensitive methods may be used when screening is performed shortly before transfusion.

Screening Methods Used by Blood Suppliers

Two culture systems have been licensed in Europe and North America to detect bacterial contamination in platelets, the BacT/ALERT system and the Pall Bacterial Detection System. The Scansystem, a more rapid method using solid phase laser cytometry, has been approved for use both in Europe and the United States. Another more rapid method that has been approved for use in Europe is based on the use of dielectrophoresis.

BacT/ALERT System

The BacT/ALERT system uses liquid media with a sensor at the bottom of the culture bottles that changes color when CO_2 is produced as a result of bacterial growth. The bottles are inoculated with 4 to 10 mL of platelet samples, incubated at 37°C for 1 to 7 days, and are automatically examined every 10 minutes by computer software that records the color change in the sensor. This system is not completely closed because the bottles are inoculated with needles.[91] The BacT/ALERT system is highly sensitive, with levels of detection of 1 to 10 CFU/mL.[91–93] Table 47–3 shows the results of routine platelet screening by several blood suppliers in Europe and North America using this system.[3,94–100]

The BacT/ALERT system has been used for bacterial testing of both apheresis platelets and WBPD concentrates prepared by the buffy-coat method. However, detection of bacterial contamination in WBDPs produced by the platelet-rich plasma method is problematic because prestorage pooling of these platelets is not permitted in some countries (e.g., Canada), and culturing individual units is costly and signifi-

Table 47–2 **Methods Used for Detection of Bacterial Contamination in Platelets**

Time of Sampling	Method	Volume Used (mL)	Detection Time (hours)	Sensitivity (CFU/mL)	Specificity

Screening of 1061 outdated platelets yielded 2 false negatives (1/531).[100]

cantly reduces the platelet unit content. The Hong Kong Red Cross developed a pooled culture method that involves stripping of five platelet segments, which are disinfected before collecting a sample of pooled platelets that is inoculated into a BacT/ALERT culture bottle.[101,102] This method was modified, validated, and adopted by one Canadian Blood Services Center.[103] An adaptation to the Hong Kong method using sterile docking has also been reported.[104] Similarly, the BacT/ALERT system has been validated for the detection of bacteria in WBDPs in a pooled format by Brecher and colleagues.[92]

Because the initial inoculum of bacteria is probably very small (<10 microorganisms/mL), even a very sensitive technique will miss some contaminated units. This has been demonstrated by several reports of false-negative results in platelet units tested by the BacT/ALERT system, including one case each of *Salmonella* and *S. marcescens* in Canada, a case of *S. lugdunensis* in the United States,[50] and two cases of *Bacillus cereus* in the Netherlands,[105] all of which resulted in severe or fatal reactions.

To evaluate the incidence of false negatives using the BacT/ALERT system, the Copenhagen Blood Transfusion Service Center conducted a trial with 946 buffy-coat–derived platelet units. Bacterial cultures were performed immediately after platelet production and repeated after 7 or more days of storage. This study reported that 0.63% of units that were negative on initial culture were positive during the later second screening, most of them contaminated with coagulase-negative staphylococci.[3] A similar study was conducted in Norway, from 2002 to 2004. Two out of 1061 outdated platelets were contaminated with *Bacillus* spp. and *S. epidermidis,* which were missed in the initial bacterial cultures.[100] Likewise, during the implementation of bacterial testing of pooled platelets at the Hong Kong Red Cross, it was shown that BacT/ALERT cultures missed initial positive cultures in units contaminated with *P. acnes* and coagulase-negative staphylococci.[102] These studies demonstrate that the BacT/ALERT system may not be sufficiently sensitive to pick up low levels of bacterial contamination.

Most centers are routinely testing for aerobic bacteria, because the majority of clinically significant organisms belong to this group. However, there are reports of transfusion reactions due to the presence of *P. acnes*.[32] It is also true that some bacteria commonly found as platelet contaminants (e.g., some *Streptococcus* spp.) can grow better in anaerobic culture media. The question of whether it is worthwhile to also implement anaerobic bacterial cultures is subject to ongoing debate.

Recently, the FDA cleared Gambro BCT's apheresis platelet technology for routine storage and transfusion for up to 7 days when bacterial testing is done using the BacT/ALERT system as a release test. Based on a pilot study that was conducted from March to October 2004, a standardized sampling and testing protocol has been described by Gambro BCT. To implement transfusion of 7-day platelets, blood centers need to follow the optimized protocol and obtain proper FDA approvals to use the BacT/ALERT system as a release test.[106] This approach will likely reduce platelet outdating, ensuring a more adequate platelet supply. It has been shown that platelets stored for up to 7 days retain acceptable in vitro functionality.[107] In vivo effectiveness of these platelets has also been demonstrated in an autologous transfusion model using healthy volunteers.

The Pall Bacterial Detection System (BDS)

This culture method uses the decrease in oxygen concentration as an indicator of bacterial growth in platelets. Approximately 6 mL of platelet samples are passed through the filter of this closed system to remove remaining leukocytes and platelets and allow 50% of bacteria to pass with the plasma into an incubation bag. After 24 to 30 hours of incubation, the oxygen concentration of this bag is measured with an oximeter. A decrease in the percent of oxygen to 19.5% or less is indicative of bacterial growth.[91] This system detects gram-positive and gram-negative bacteria at the levels of 100 to 500 CFU/mL with a sensitivity of 96.5%.[108] Recently, an enhanced Pall detection system (eBDS) has been developed, which does not have the platelet-retaining filter, allowing for improved bacterial recovery and sensitivity.[109]

The U.S. Blood Centers of the Pacific have implemented bacterial detection of platelets using the Pall BDS system. Out of 15,823 screened units, 1 containing coagulase-negative staphylococci was missed by this system and transfused, causing a moderate febrile transfusion reaction in the recipient.[110]

The Pall eBDS system has also been validated for bacterial detection in leukoreduced RBCs. In a study of this system, 270 RBC units were spiked with eight bacteria to final concentrations of 10 and 100 CFU/mL before storage at 4°C for up to 6 weeks. Samples were taken weekly and evaluated by the Pall system. The only bacterium that exponentially increased in concentration over the 6-week period of this study was *Y. enterocolitica*. *P. aeruginosa* and *S. epidermidis* did not increase in concentration but survived at a constant concentration during the whole study. The other bacterial species studied slowly decreased over the course of the study. Nonetheless, the results of this study suggest that the Pall eBDS system may be suitable for bacterial detection in RBCs.[111]

Scansystem

The Scansystem method involves testing a leukoreduced platelet sample that is mixed with a solution containing both a platelet aggregation agent and a DNA labeling dye. After 40 minutes of incubation, the mixture is passed through a filter that retains the aggregated platelets. The flowthrough solution containing bacteria is then further incubated for 20 minutes before filtration through a 0.4-μm black membrane that captures the fluorescently labeled bacteria. The black membrane is then placed on the analyzer (solid phase cytometer), which uses a laser light to detect any fluorescent signals. Positive signals on the membrane are manually confirmed using a microscope. Results are obtained within 90 minutes of sample processing.[91,112,113] The Scansystem has been used for the bacterial screening of platelets at the Belgium Red Cross (La Louvière Blood Center, Belgium) since March 2005, at the Kuwait City Blood Bank since June 2005, and at the German Red Cross (Munster Blood Bank, Munster, Germany) since 2004 (Agnès Bouyé, Marketing Director, HEMOSYSTEM, personal communication).

The Scansystem has been recently modified for bacterial detection in RBCs. This method involves the agglutination and removal of RBCs from the sample followed by bacteria labeling and final recovery on a black membrane for analysis using the cytometer. The entire test can also be completed in 90 minutes and has been shown to be very sensitive for detecting gram-positive and gram-negative bacteria at levels of 1 to 10 CFU/mL.[114]

Dielectrophoresis

Dielectrophoresis is based on the observation that cells placed in nonuniform electric fields move toward electrodes, as determined by their dielectric properties. Bacteria are released from the electrodes when the electric field is discontinued. Levels of bacteria detected by this system vary between 10^3 and 10^5 CFU/mL.[91]

Screening Methods for Use Prior to Transfusion

The number of bacteria in blood components associated with severe transfusion reactions is usually greater than 10^6 CFU/mL. Therefore, a less sensitive technique may be adequate to detect clinically significant contamination in the hospital transfusion service immediately before transfusion. However, such a test would have to be rapid to avoid delaying product issue. Also, it should not require specialized equipment or specially trained personnel. In addition, the test should be specific to avoid blood wastage or delays in product issue. Unfortunately, screening methods currently used shortly before transfusion are typically subjective, nonsensitive, and/or complex and time consuming.

Microscopic Examination

Microscopic observation of platelet smears using Gram staining, acridine orange, or fluorophores usually yield positive results at bacterial concentrations greater than 10^6 CFU/mL.[91] However, such methods require specific reagents, complex equipment, and/or skilled personnel. Because some hospital laboratories have Wright staining equipment, they can perform an initial identification of bacterial contamination, which can be followed by Gram classification.[91]

Multireagent Strip Testing

Because most bacteria metabolize glucose, thereby producing acid that causes a decrease in pH, diminished pH and glucose levels can be expected in platelet units contaminated with bacteria. Several studies have investigated the use of multireagent

strips for the rapid detection of decreased pH and glucose levels as indicators of bacterial contamination in platelets. The sensitivity of this method is very low, with levels of detection on the order of 10^7 to 10^8 CFU/mL of bacteria. Because the tested parameters may change due to multiple factors (e.g., presence of certain anticoagulants, increase in pH after glucose exhaustion), a major disadvantage of this method is its low specificity, which may result in platelet wasting.[91] The use of a pH meter to measure pH has also proven to be inaccurate, with many false positives causing product wasting, especially in units with high WBC and platelet content.[115]

Visual Examination

Bacterial proliferation in RBC units causes decreased oxygen and glucose concentrations, which in turn leads to RBC hemolysis. Darkening of RBC units due to hemolysis has been used as a screening method for bacterial contamination, although sensitivity is relatively poor.

Due to their discoid morphology, platelets reflect light and produce a "streaming" phenomenon (swirling). Bacterial contamination of platelets causes a decrease in pH, resulting in the loss of the swirling effect. Swirling loss is nonspecific, because it is often associated with conditions other than the presence of bacteria.

These visual inspection methods are very subjective and have very low sensitivity, which means that low levels of clinically significant bacteria would usually be missed. The low specificity of these techniques is also problematic; it has been reported that RBCs and platelets that are close to the end of their shelf life present darkening and decreased swirling, respectively, in spite of not being contaminated with bacteria.[91]

Screening Methods under Development

Several systems for the detection of bacterial contaminants in blood components are under development. Due to their high rapidity, sensitivity, and specificity, molecular methods such as nonamplified chemiluminiscence-linked rRNA probes or PCR-based methods[89] are very attractive. However, bacterial contamination of laboratory reagents and materials, as well as common bacterial sequences found in human blood, complicate the use of these techniques. Recent studies have shown promising results using reverse transcriptase PCR methods that minimize the risk of amplifying genetic material from dead bacterial cells.[116,117]

Rapid-detection systems that are under development include the BUG's BEADS system, which uses magnetic beads coupled with PCR; an enzyme immunoassay to detect peptidoglycan; and an immunoassay developed by Verax Biomedical. All of these systems have a sensitivity of greater than 10^3 CFU/mL.[2,118]

One important factor to consider when optimizing molecular techniques is that due to their complexity, it would be difficult to implement such technology in a wide range of blood centers or transfusion services.

Limitation of Component Storage

Most severe septic transfusion reactions occur with RBCs stored for longer than 21 days and platelet concentrates stored for longer than 3 days. In 1986, the FDA reduced the platelet storage time from 7 to 5 days because of concern about the increasing number of case reports of platelet-associated sepsis occurring with concentrates transfused after 5, 6, or 7 days of storage.[119]

Apheresis Platelets versus Random Platelet Concentrates

Apheresis platelets have a lower risk of being contaminated than pooled platelets since they are collected from a single donor. A 12-year prospective study conducted by Ness and Campbell-Lee[120] showed that the incidence of septic platelet transfusion reactions decreased from 1 in 4818 to 1 in 15,098 when the use of single-donor apheresis platelets increased from 51.7% to 99.4% in their institution. The authors also observed that the rate of septic reactions was five times higher in recipients of pooled platelets than in recipients of single-donor platelets. These septic events were clinically serious; 4 out of 23 cases (17.4%) were fatal.

Leukocyte Reduction

Phagocytes may be important in the elimination of viable bacteria present in blood components during the first few hours after venipuncture.[121] In the case of organisms such as *Y. enterocolitica*, the bacteria may already be present in the phagocytes in the donor's blood; with bacteria introduced from the donor's skin, phagocytosis may occur during initial storage, particularly if there is a room temperature hold for several hours before refrigeration. Bacteria may then either be released back into the blood component as the leukocytes disintegrate during storage, or they may be eliminated by prestorage leukodepletion. Several spiking experiments have demonstrated reduced bacterial growth of *Y. enterocolitica* in contaminated RBC units that were leukoreduced in the hours after controlled contamination.[122,123] Data on the efficacy of leukoreduction in preventing growth of other bacterial strains in RBC or platelet concentrates have been less conclusive.[122]

Temperature and Time of Storage before Component Preparation

There is marked variability among countries with regard to the time and temperature of whole blood storage before component preparation. Time and temperature of storage may influence bacterial growth, extent of phagocytosis, and the occurrence of complement-mediated killing. The few studies done on this subject have come to varying conclusions, possibly because of confounding variables such as differences in component preparation methods and leukoreduction.[124–126]

Lowering Component Storage Temperature

Platelet storage at room temperature maintains platelet hemostatic efficacy, but this temperature provides a hospitable culture medium for many bacteria. The development of various storage solutions that putatively permit retention of platelet function at 4°C could considerably decrease bacterial growth in platelets. For example, glycolysation of platelets with uridine diphosphate-galactose prior to chilling prevents platelet early sequestration, a typical drawback of cold-stored platelets.[127] Another recent approach was the addition of a solution of trehalose and phosphate to platelets, which experimentally appears to be effective in protecting platelet structure and function during cryopreservation.[128] Investigators have also found that the proliferation of *Y. enterocolitica* in RBCs may be decreased by storage at 0°C.[129] This interesting approach needs further evaluation.

Water Bath Disinfection

Water baths used for thawing plasma and cryoprecipitate should be emptied and disinfected weekly, to prevent the heavy growth of organisms such as *B. cepacia* and *P. aeruginosa*. Plasma and cryoprecipitate units should also be kept dry during thawing by use of a plastic overwrap.[59]

Photochemical Treatment (PCT) to Achieve Pathogen Inactivation

The best studied methodology for pathogen inactivation of platelets is use of the combination of the psoralen amotosalen HCl with long-wavelength ultraviolet light (UVA).[130] After being subjected to large phase III clinical trials in Europe and the United States, the commercial product based on this methodology, INTERCEPT Blood System for Platelets, has been introduced on a limited scale in some blood centers in Europe (Belgium, Italy, Norway, Portugal, Spain, and Sweden).[3]

Another PCT methodology combines riboflavin and UVA illumination. Using a light dose of 6.2 J/mL, this method can inactivate from 4 to 6 logs of *S. epidermidis* and *E. coli* without disrupting in vitro platelet functionality.[27] This process has not yet been studied in randomized, controlled clinical trials.

In addition to the inactivation of bacteria, both of these PCT approaches have been shown to inactivate other bloodborne pathogens in platelet concentrates, making these systems potentially very attractive to ensure blood safety. Nevertheless, before the worldwide implementation of a pathogen inactivation method, it has to be shown to be safe, efficacious, and cost effective.[3,27,28]

PREFERRED APPROACH

Hospital Transfusion Service

A high index of suspicion is necessary to correctly diagnose a transfusion-associated septic reaction. If a septic reaction is suspected, the blood product transfusion should be stopped and an intravenous line for venous access should be left in place. The blood bag should be returned to the blood bank and inspected for evidence of color change, hemolysis, clots, or bag defects. A Gram stain should be done on the remaining blood component, although this test may be negative in one third of cases due to insensitivity of the technique. Aerobic and anaerobic cultures of the remaining product should also be performed. Nutrient broth may be introduced into the blood bag if very little product remains for culture. Blood cultures also should be taken from the recipient. Symptoms are often nonspecific, so, in the case of a severe reaction, serologic investigation to rule out an acute hemolytic reaction due to an immunologic incompatibility should also be done.

For patients suspected of having a transfusion-associated septic reaction, broad-spectrum antibiotic coverage should be initiated even before culture results are obtained. Aggressive supportive care with intravenous fluids and vasopressors may be necessary if septic shock occurs.

Ideally, the diagnosis is firmly established when the same organism is isolated from both the blood component and the patient. In some studies, microbial identity has been determined with the use of antibiotic susceptibility tests and fingerprinting methods. Laboratory diagnosis can be difficult, because cultures from a recipient who is taking antibiotics may be negative, and cultures of the remaining blood component may be positive due to post-transfusion contamination. The detection of an unusual pathogen in a transfusion recipient should prompt a search for a possible contaminated blood component. Clustering of cases of septicemia with unusual organisms should initiate a search for contaminated blood components or another iatrogenic cause (e.g., contaminated saline solutions). Finally, the blood supplier should be informed as soon as possible about the suspected transfusion-associated septic reaction.

The AABB issued a document in February 2005 to alert clinicians of the risk of septic transfusion reactions due to bacterially contaminated platelet units.[131] This document outlines procedures for the management of patients receiving platelet transfusions and the management of donors referred for follow-up after a donated platelet unit has been found positive for bacterial contamination. In all cases, the AABB urges that clinicians collaborate with hospital transfusion service, blood collection center, and health department when notification is necessary. It is important to note that a survey of infectious diseases consultants, conducted by the Infectious Diseases Society of America in 2004, showed that only 36% of respondents were aware of transfusion-associated septic reactions.[50] It is therefore essential that clinicians are educated to recognize, notify, and appropriately manage patients suspected of receiving blood components with bacterial contamination.

Blood Supplier

When informed of a possible septic transfusion reaction, the transfusion service should recall and culture the other components from the same donation. If a defect is found in the bag or a cluster of cases has been reported, quarantine and investigation of other products from the same lot may be necessary. In the case of an organism that is not part of the normal skin flora, the donor should be contacted and asked about the development of infections before or shortly after blood donation.

In October 2004, the AABB issued Bulletin No.04–07 to provide guidelines for the follow-up of initial positive tests for possible bacterially contaminated platelet units.[132] This document strongly recommends that all blood centers have standardized definitions when referring to the bacterial testing of platelets. Similarly, AABB bulletin No.05–02 was issued in January 2005 as guidance for managing platelet donors with positive or abnormal results on bacterial detection testing.[133] According to this bulletin, donor notification of an initially positive result is indicated if the donor is suspected to be infected with pathogenic bacteria. Donor referral should be based on medical judgment once confirmatory results are obtained and the microorganism identified is considered to be dangerous for either the donor and/or the recipient.

Transfusion services should encourage the hospitals they serve to report septic transfusion reactions, and they in turn should report such reactions to national registries. Estimates of the frequency of such reactions are an important part of transfusion medicine hemovigilance, in order to continue to improve the safety of the blood supply.

Chapter 48

Other Viral, Bacterial, Parasitic and Prion-Based Infectious Complications

Jay E. Menitove • Gary E. Tegtmeier

INTRODUCTION

During the last decade of the 20th century, diagnostic advancements dramatically reduced the transmission of human immunodeficiency virus (HIV), hepatitis C virus (HCV), and hepatitis B virus (HBV) by transfusion. However, simultaneously, the emergence of additional pathogens as potential blood contaminants gained attention. Some of these agents represented newly discovered entities (e.g., severe acute respiratory syndrome [SARS-CoA]). Others were known sources of transfusion complications that expanded into the United States (e.g., Chagas disease). Additionally, some agents demonstrated species jumping from animal hosts to humans (e.g., variant Creutzfeldt-Jakob disease [VCJD], Asian influenza, and West Nile virus). Increasing globalization through commerce, travel, and social interaction requires that many infectious agents, once thought exotic or of remote significance, must be considered as potential blood-component contaminants.[1,2] Alternatively, new information may reduce some concerns. For example, porcine endogenous retrovirus (PERV), previously linked to humans undergoing xenotransplantation, currently appears less threatening.[3]

This chapter addresses agents endemic to the United States and those emerging in other parts of the world that have been transmitted or are theoretically capable of transmission by transfusion, and approaches to reduce the associated risks.

BABESIA

Babesiosis, a zoonosis caused by the rodent-borne piroplasm protozoan, *Babesia microti*, is transmitted by *Ixodes scapularis*, the deer or black-legged tick. *I. scapularis* also transmits the agents of Lyme disease and human granulocyte ehrlichiosis (discussed later).[4–10]

The white-footed mouse (*Peromyscus leucopus*) is the natural reservoir for *B. microti*; once infected, a mouse remains parasitemic indefinitely. *I. scapularis* transmits the piroplasm most frequently during the nymphal stage when the tick is 1.5 mm long. Tick bites, at this stage, often go unnoticed despite the 48- to 72-hour feeding time during which infection occurs.[11] *B. microti* is the agent most frequently associated with clinical illness; MO1-type, WA1-type, and CA1-type also cause clinical disease.[12,13] Endemic areas include coastal and island areas of New England and New York as well as parts of California, Washington, Missouri, Wisconsin, and Minnesota.[6,7,9,12,13] Ticks coinfected with *B. microti* and *Borrelia burgdorferi* (the agent of Lyme disease) transmit *B. microti* less frequently than *B. burgdorferi* because the tick is a less competent host for *B. microti*. The intraerythrocytic localization of *B. microti*, however, favors transfusion transmission of this agent over that of *B. burgdorferi*.[6]

In humans, circulating *B. microti* DNA persists, on average, for 82 days in asymptomatic patients and in those not given specific treatment. Co-infection with Lyme disease does not alter the duration of parasitemia. Parasites circulate for only 16 days in persons who are treated with clindamycin and quinine; alternative antibiotic regimens include atovaquone and azithromycin.[13] Silent *Babesia* infections occur commonly. Some infected individuals develop a chronic carrier state lasing months to years. In others, recrudescence occurs spontaneously or after splenectomy or immunosuppression.[11,14] The parasite retains infectivity in red blood cell (RBC) components at refrigerated or frozen temperatures and in the residual RBCs contained in platelet concentrates stored at room temperature.[5,8]

To date, more than 50 post-transfusion cases involving *B. microti* and other *Babesia* species have been reported.[5,6,9,12,15] Several reports involve donors who transmitted infections through multiple donations given up to 6 months apart.[11,16] The overall risk of acquiring transfusion-associated babesiosis is low, but varies regionally. In Connecticut, 1.9% of seronegative donors became seropositive on a subsequent donation. In another study, 0.9% of donors in endemic and nonendemic areas of Connecticut had confirmatory indirect immunofluorescence assay (IFA)-positive test results for *Babesia* infection; the prevalence rates peaked in July when 1.2% of donors were seropositive.[15] This represents a relatively high potential threat in an endemic area because 8 of 51 recipients became seropositive after receiving blood from IFA-positive blood donors.[17]

Asplenia, older age, immunodeficiency, organ transplantation, and liver disease increase the risk of severe *Babesia* illness. In acute symptomatic cases, fatigue, malaise, weakness, and fever occur in more than 90% of the patients. Shaking chills, diaphoresis, nausea, anorexia, headaches, and myalgia occur frequently. Heart murmurs, hepatomegaly, and splenomegaly are found in 10% to 20% of patients; jaundice occurs less frequently. Renal failure, disseminated intravascular coagulation, and adult respiratory distress syndrome have been reported.[13] The average hemoglobin concentration was 11.3 g/dL in a review of hospitalized patients with community-acquired babesiosis.[4]

Examination of blood smears for intraerythrocytic ring forms and maltese cross–like tetrads (including more than two parasites per cell, contorted shapes, vacuoles, and

budding),[18] antibabesial antibody assays, and polymerase chain reaction (PCR) assays for babesial DNA provide laboratory evidence of infection.[4,14] (Fig. 48–1)

Most transfusion-associated babesia cases involve RBC transfusions, although frozen-deglycerolized RBC and platelet units have been implemented.[5,8,13] Transfusion-acquired cases have an incubation period of 2 to 6.5 weeks.[4,6,8,13,15] Blood-collection agencies ask all prospective donors whether they have ever had babesiosis. Those answering affirmatively are deferred. However, donors are not asked about a recent history of tick bites or geographic residence because of the low predictive value associated with these questions. For example, 0.4% of donors in Connecticut reporting tick bites were seropositive for babesiosis antibodies compared with 0.3% in those not reporting tick bites.[9] Serologic or PCR testing is impractical at this time. The absence of specific interventions to interdict donors capable of transmitting *Babesia* infections relegates clinical awareness and prompt antibiotic therapy as the primary modality for treating this infrequent complication of transfusion therapy.

LYME DISEASE

The *Borrelia burgdorferi* spirochete causes Lyme disease, a tick-borne zoonosis present in mice, squirrels, and other small animals. More than 20,000 human Lyme disease cases occur annually in the United States, although none has been associated with transfusion. Endemic areas include the northeastern, mid-Atlantic, and upper north-central regions of the United States.[10,19]

Ixodes scapularis, the black legged deer tick, transmits *B. burgdorferi* in the northeastern and north-central parts of the United States. *I. pacificus,* the western black-legged tick, transmits the infection along the Pacific Coast. The ticks feed predominantly in the late spring and early summer during their nymphal stage, and Lyme disease usually results from bites of infected nymphs. Deer do not become infected but rather transport and maintain the ticks.[10]

Patients with Lyme disease typically present with a characteristic erythema migrans rash accompanied by fever, malaise, headaches, myalgia, arthralgia, or Bell's palsy. The rash occurs 3 to 30 days after a tick bite. *B. burgdorferi* spirochetes disseminate from the entry site via cutaneous, lymphatic, and blood-borne routes. In one study, spirochetes were isolated from the blood of 44% of patients with symptomatic Lyme disease.[20] *B. burgdorferi* has also been isolated from erythema migrans lesions.

The diagnosis of Lyme disease is based primarily on characteristic symptoms, physical examination findings, and a history of possible tick exposure.[10,20–23] Serologic tests, including enzyme-linked immunoassays and IFA tests, become positive 4 to 6 weeks after infection. Western blot testing is used to confirm the results of reactive screening tests. Treatment with antibiotics clears the infection, but additional treatment to relieve symptoms is prescribed when arthritis persists after two antibiotic courses and for post–Lyme disease syndrome.[20–23]

Despite documentation that the spirochete survives routine RBC and frozen plasma storage, testing blood donors is not under consideration because no reports exist of transfusion-associated Lyme disease.[10] Of note, transfusion of RBCs or platelets collected during peak deer tick activity to 155 patients undergoing cardiothoracic surgery resulted in no serologic or clinical evidence of Lyme disease.[5] Individuals with a history of Lyme disease are accepted as blood donors provided they have been treated and are asymptomatic 12 months after the last dose of antibiotics.

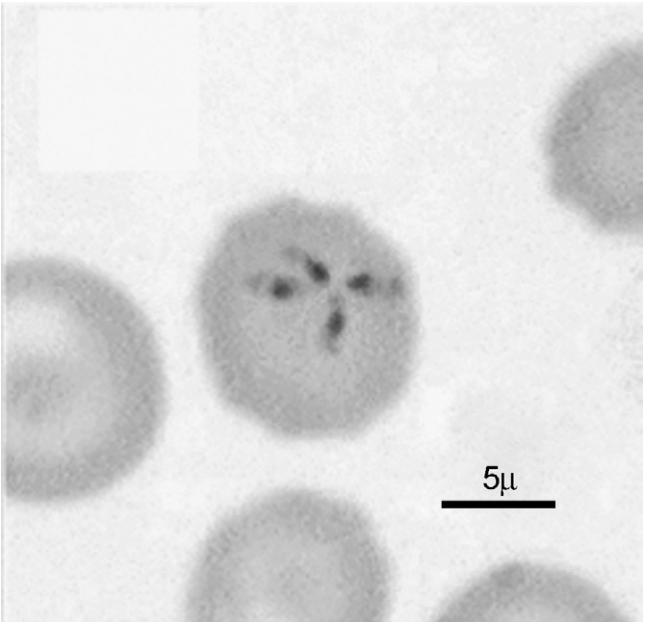

Figure 48–1 *Babesia microti* parasites infect up to 5% of red cells. Although more common in infections with *B. gibsoni* (WA-1) than *B. microti,* tetrad or Maltese cross structures are pathognomonic for *Babesia* infections. They result from budding with four nucleated intraerythrocytic merozoites remaining attached to each other after division. (From Pantanowitz L, Monahan-Earley R, Dvorak A, et al. Morphologic hallmarks of *Babesia*. Transfusion 2002;42:1389.)

TRANSFUSION TRANSMISSION OF OTHER TICK-BORNE PATHOGENS

The rickettsial agents human monocytic ehrlichiosis (HME) and human granulocytic ehrlichiosis (HGE) are intracellular organisms that survive in stored blood and cause mild to severe illnesses.[10] *Ehrlichia chaffeensis* causes HME and is transmitted to humans through the bite of the Lone Star tick (*Amblyomma americanum*) previously infected by contact with deer or possibly dogs.[9,10] Most of the reported cases have occurred in the south-central and southeastern United States.

Anaplasma phagocytophila causes HGE and is related closely to species infecting horses (*Ehrlichia equi)* or ruminants (*Ehrlichia phagocytophila*). This illness occurs predominantly in the northeastern, upper midwestern, and northwestern areas of the United States and is transmitted to humans by *I. scapularis* or *I. pacificus* ticks.[5,9,24–26] Fifty percent of ticks examined in one study in Connecticut were infected with the HGE agent, but none was infected with *E. chaffeensis.*[27]

Patients with HME and HGE present similarly, with fever, headache, myalgia, thrombocytopenia, leukopenia, and elevated liver enzyme concentrations. A rash occurs in one third of patients with HME but in fewer patients with HGE. Membrane-bound intracytoplasmic ehrlichia aggregates, or morulae, are present in monocytes. Complications include respiratory distress, renal failure, neurologic disorders, and disseminated intravascular coagulation. Septicemia, vasculitis,

and thrombotic thrombocytopenic purpura should be considered in the differential diagnosis.[5,10,24,25] Doxycycline is the treatment of choice.

Because ehrlichia are present in blood, transfusion transmission must be considered. One case of transfusion-associated HGE occurred 9 days after an RBC transfusion donated by an asymptomatic donor who had been exposed to extensive deer ticks 2 months previously. The infected RBCs were stored for 30 days before transfusion.[28] An in vitro study suggested that leukocyte reduction may not be completely effective at preventing *E. chaffeensis* transmission because some pathogens are found in the cell free plasma fraction.[29]

An extensive epidemiologic study in Arkansas involving military trainee blood donors who had been exposed to tick bites and unknowingly infected with the agents of ehrlichiosis and Rocky Mountain spotted fever (RMSF) found no clinical illness among the recipients of RBCs and platelets donated by these soldiers. However, possible seroconversion to RMSF occurred in one of the recipients.[30]

A single case report has been published of clinical illness associated with transfusion-transmitted RMSF infection. The donor developed symptoms of RMSF 3 days after donation and died 6 days later. The recipient, who developed fever and headache 6 days after receiving the implicated *Rickettsia rickettsii*–infected transfusion, was notified about the donor's illness and was treated effectively.[10]

Other tick-borne agents implicated in transfusion-associated cases include Colorado tick fever virus and tick-borne encephalitis virus.[10] Although the risk of transfusion transmission of these agents is low, clinical suspicion is important as a mechanism for determining infection by these organisms.

MALARIA

Etiology, Life Cycle, Diagnosis

Malaria is a protozoan disease caused by four species of the genus *Plasmodium: P. falciparum, P. vivax, P. ovale,* and *P. malariae* (Table 48–1). These protozoa are transmitted to humans by the bite of an infected female mosquito of the genus *Anopheles*. Infection of the human host, absent treatment, results in a chronic intraerythrocytic infection that can be transmitted by blood transfusion.

The two-host life cycle of the malaria parasite is diagrammed in Figure 48–2.

Although the signs and symptoms of malaria are variable, most patients are febrile, and many also manifest headache, chills, sweating, nausea, vomiting, diarrhea, back pain, myalgia, and cough. A diagnosis of malaria should be considered for any patient with these symptoms who has a history of travel to a malaria-endemic area or recent blood transfusion. Given the periodic reports of local mosquito-borne transmission, malaria should also be considered in the differential diagnosis of patients who have fever of unknown origin regardless of their travel history.

Malaria is diagnosed microscopically by finding intraerythrocytic parasites on Giemsa-stained peripheral blood smears. Properly prepared thick and thin smears must be examined by trained laboratory personnel to make an accurate laboratory diagnosis. Patients with negative smears suspected of having malaria should have additional smears examined daily for 3 days. PCR can be a useful adjunct in cases in which serial testing of smears yields negative results.

Epidemiology

Malaria is a huge global public health problem with an estimated annual incidence of 300 to 500 million cases and 3 million deaths per year.[31] Malaria-endemic areas include parts of Africa, Asia, Central America, Hispaniola, North America, Oceania, and South America.

During the early part of the 20th century, specifically 1914, an estimated 600,000 cases of malaria occurred in the continental United States, but since the 1940s, improved socioeconomic conditions, water management, vector control, and case management have prevented endemic malaria transmission.[32] Ongoing malaria surveillance in the United States by the Centers for Disease Control and Prevention (CDC) continues to identify cases in immigrants and in residents and travelers to areas of the world where malaria transmission still occurs. Additionally, each year, a few cases are reported that might represent local mosquito-borne transmission.[33] For example, seven cases of locally acquired, mosquito-transmitted *P. vivax* malaria were reported in Palm Beach County, Florida. Multilocus genotyping of the ribosomal RNA of the isolates from the seven patients revealed that they were infected by the same strain.[34] Congenital infections and transfusion-acquired infections round out the sources of malaria cases diagnosed each year in the United States.

Of 1337 cases of malaria in the United States with onset of symptoms in 2002, one was due to transmission of *P. malariae* by blood transfusion.[35] Of 1278 cases reported in 2003, one was due to transmission of *P. falciparum* after a blood transfusion.[36] The overwhelming majority of reported cases in both years were imported (i.e., acquired outside the United States).

Data from 1979 through 1986 showed that cases were more frequently identified in foreign civilians than in U.S. civilians.

Table 48–1 **Transfusion-transmitted Malaria in the United States 1963–2004***

	Plasmodium falciparum	*Plasmodium vivax*	*Plasmodium ovale*	*Plasmodium malariae*
Transfusion-associated cases, 1963–2004 (% of total)	34 (36%)	25 (27%)	5 (5%)	26 (28%)
Average incubation period (days)	17 (range, 8–36)	20 (range, 11–42)	24 (range, 18–30)	51 (range, 8–90)
Relapse	No (manifests clinically within 1 yr)	Yes (usually within 3 yr)	Yes (usually within 3 yr)	Yes (prolonged)

*Three cases were due to mixed infections. The etiologies of two cases were unknown.

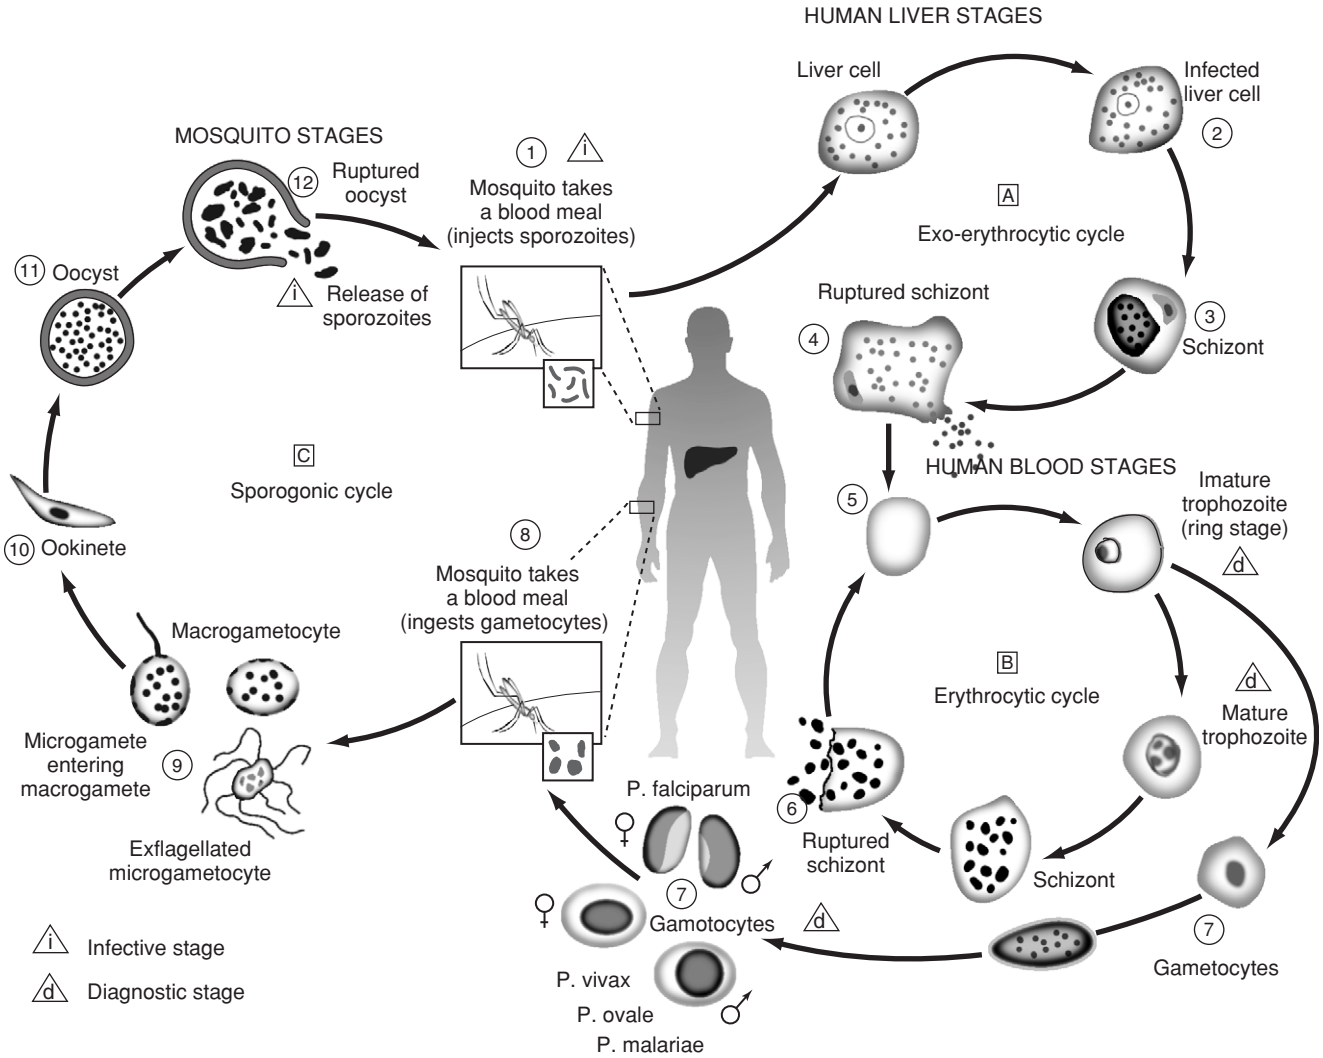

Figure 48–2 The malaria parasite life cycle involves two hosts. During a blood meal, a malaria-infected female *Anopheles* mosquito inoculates sporozoites into the human host. Sporozoites infect liver cells and mature into schizonts, which rupture and release merozoites. (Of note, in *Plasmodium vivax* and *P. ovale,* a dormant stage [hypnozoites] can persist in the liver and cause relapses by invading the bloodstream weeks, or even years later.) After this initial replication in the liver (exo-erythrocytic schizogony), the parasites undergo asexual multiplication in the erythrocytes (erythrocytic schizogony). Merozoites infect red blood cells. The ring-stage trophozoites mature into schizonts, which rupture, releasing merozoites. Some parasites differentiate into sexual erythrocytic stages (gametocytes). Blood-stage parasites are responsible for the clinical manifestations of the disease. The gametocytes, male (microgametocytes) and female (macrogametocytes), are ingested by an *Anopheles* mosquito during a blood meal. The parasites' multiplication in the mosquito is known as the sporogonic cycle. While in the mosquito's stomach, the microgametes penetrate the macrogametes, generating zygotes. The zygotes in turn become motile and elongated (ookinetes) and invade the midgut wall of the mosquito where they develop into oocysts. The oocysts grow, rupture, and release sporozoites, which make their way to the mosquito's salivary glands. Inoculation of the sporozoites into a new human host perpetuates the malaria life cycle. (Figure and legend are taken from the Centers for Disease Control and Prevention [CDC] website http://www.cdc.gov/malaria/biology/life_cycle.htm.)

However, since 1997, the situation has reversed. Cases in United States civilians are now reported at 2.5 to 3 times the number in foreign civilians, most likely due to increased travel by U.S. civilians to endemic areas and decreased immigration since 2001.[36] From 75% to 90% of the cases among U.S. civilian travelers occurs in persons who failed to take prophylactic drugs, had not taken CDC-recommended drugs, or were noncompliant with a recommended drug.

Mosquitoes of the genus *Anopheles*, with few exceptions, feed between dusk and dawn. The exceptions are daytime feedings in densely shaded woodlands or dark interiors of houses or shelters. Therefore, travelers who visit malarial areas during bright daylight hours are at little or no risk for acquiring malaria if they return to a nonmalarial area before dusk.

Transmission by Transfusion and Risk Reduction

Transfusion-transmitted malaria occurs at an estimated rate of 0.25 cases per 1 million blood units collected.[37] Because of this low incidence and the lack of a laboratory test approved by the U.S. Food and Drug Administration (FDA), prevention of transfusion-transmitted malaria continues to depend solely on the donor-deferral guidelines established by the FDA and most recently updated in 1994.[38] Currently, prospective donors who are residents of countries where malaria is not endemic but who have traveled to a malaria-endemic area are temporarily deferred until 1 year after their departure from the endemic area if they have remained free of symptoms suggestive of malaria. Immigrants, refugees, citizens, and residents of malaria-endemic areas are deferred for 3 years after

their departure from the endemic area if they have remained free of symptoms suggestive of malaria. Prospective donors who were diagnosed and treated for malaria are deferred for 3 years after becoming asymptomatic.

Between 1996 and 1998, three cases of post-transfusion malaria due to *P. falciparum,* two of which were fatal,[39] were diagnosed in the United States, prompting a review by the CDC of all cases of transfusion-transmitted malaria reported between 1963 and 1999[40] (see Table 48-1, which has been updated to include reported cases in 2002 and 2003[35,36]). In total, 95 cases (2.5 per year) were reported through 2003. Thirty-four (36%) cases were caused by *P. falciparum*, 25 (27%) by *P. vivax*, 26 (28%) by *P. malariae*, 5 (5%) by *P. ovale*, 3 (3%) by mixed species, and 2 (2%) by an undetermined species. *P. falciparum* cases increased in frequency over the period 1990 to 2003, accounting for 11 (73%) of 15 cases during that interval, compared with 15 (24%) of 62 cases reported between 1970 and 1989. Of 10 (11%) fatal cases overall, 6 were associated with *P. falciparum*, 2 with *P. vivax*, and 2 with *P. malariae*.

The incubation period in these cases ranged from 8 to 90 days, with *P. falciparum* having the shortest time (mean, 17 days; range, 8 to 36 days) and *P. malariae* having the longest (mean, 51 days; range, 8 to 90 days). The period between onset of symptoms and the time of diagnosis ranged from 1 to 180 days, with a median of 10 days. Ninety-four percent of the cases were associated with transfusion of whole blood or RBCs; 6% were platelet-associated.

Implicated donors were defined as having met one or more of the following criteria (1) a blood smear that demonstrated malaria parasites, (2) a positive result on malaria serology, and (3) being the only donor. Ninety-three donors were implicated in the 95 cases. The median number of donors per case was seven (range, 1 to 192). Donors were overwhelmingly male (90%) and ranged in age from 19 to 59 years (median, 27 years). Foreign-born donors accounted for 60% (64% of those from Africa); 40% were born in the United States.

Of 60 donors implicated in the cases for which epidemiologic follow-up was complete, serology was the most effective tool for identifying transmitting donors (73%); only 10% were identified by a positive blood smear. Serology and blood smear were both positive in 15%, and 3% were implicated as the only donor to a case.

Analysis of all cases using current donor deferral guidelines revealed that 23 (24%) cases occurred despite proper application of the guidelines. When reviewed against the guidelines in place at the time they occurred, 3 cases could not be evaluated because their dates of onset were before 1970 when guidelines were vague; 18 of the remaining 20 cases would still have occurred, but 2 would have been prevented if then-current guidelines had been applied properly. Not surprisingly, most (65%) of the cases that occurred despite following guidelines were caused by *P. malariae*.

The continued occurrence of cases in the face of current history questions highlights the reality that malaria risk from transfusion, although low, cannot be fully prevented by questioning of donors. Although the deferral guidelines currently in place are based on the biology of the four species of *Plasmodia* that cause malaria, they represent a balance struck between maximizing safety and minimizing donor loss. *P. vivax* and *P. ovale*, species that give rise to relapsing infections, rarely persist longer than 3 years.[42] However, some infections do persist, and individuals with these prolonged infections will transmit malaria if their blood is transfused. Likewise, disease caused by *P. falciparum*, a nonrelapsing species, manifests within 1 year after departure from a malarious area 99% of the time, but a report of falciparum malaria occurring 13 years after departure from a malarious area has been published.[41] The well-known ability of *P. malariae* to persist asymptomatically for decades in some individuals further highlights the difficulty of eradicating the risk of post-transfusion malaria through questioning of donors.[42]

The AABB has advocated the use of uniform donor screening questions to elicit malaria risk from prospective donors, including questions that inquire about a history of malaria and about the prospective donor's travel history within the past 3 years. A "yes" answer to travel outside the United States and Canada triggers further inquiry to pinpoint travel destinations in malarious areas.

The FDA is in the process of revising its guidelines for deferral of blood donors because of risk of malaria. However, it is unclear when the agency will issue the new guidelines. The proposed guidelines were discussed at the FDA's Blood Products Advisory Committee meeting in June 1999.[46] In addition to retaining the provisions for donor deferral outlined in the FDA memo of July 26, 1994,[38] the revised guidelines recommend adding the following question sequence to the donor history form: (1) "Were you born in the United States?" If yes, ask: (2) "In the past 3 years, have you been outside the United States or Canada?" If the answer to (1) is no, ask: (3) "When did you arrive in the United States, and, since your arrival, have you traveled outside the United States or Canada?" If the answer to question (2) or the second question in (3) is yes, follow-up questions will be asked of the donor to determine when and which country or countries were visited. The impetus for revision of the guidelines includes the increased number of imported malaria cases in the United States, the large number of postdonation events related to malaria reported to the FDA, and the recognition that eliciting an accurate donor history is the only currently available defense against transfusion-transmitted malaria.

From time to time, proposals to test donors for evidence of malaria have been advanced, but no FDA-approved tests or policies for screening donors are currently in place. Selective screening of high-risk donors has been suggested as an alternative to universal screening.[43] Blood-smear diagnosis is both impractical and insensitive as a donor-screening technique. The IFA test is useful diagnostically but is unsuitable for large-scale donor screening, although it could be used to test high-risk donors and to determine their suitability.[43] Although antibody assays detect most individuals with parasitemia, they also are positive in treated persons who are no longer parasitemic.[44] Hence, noninfectious donors would also be deferred if selective antibody screening were implemented. PCR is a promising approach that may have the required sensitivity and specificity, but it is currently not standardized and not available outside research laboratories.[45]

CHAGAS DISEASE

Life Cycle

American trypanosomiasis, or Chagas disease, is a zoonosis caused by the hemoflagellate protozoan parasite *Trypanosoma cruzi*. The life cycle of *T. cruzi* involves transmission from

insect vectors to mammalian hosts including humans. *T. cruzi* infects humans when triatomid (reduviid) or kissing bugs ingest a blood meal from the host and deposit infected feces into the wound or when contaminated feces contact the mucosal surface of the eye or mouth. Hematogenous spread occurs subsequently. In addition, *T. cruzi* crosses the placenta and can cause congenital disease[47–51] (Fig. 48–3).

Clinical Course

Acute Chagas disease is associated with fever, facial edema, generalized lymphadenopathy, and hepatosplenomegaly. Symptomatic myocarditis and meningioencephalitis can occur, and fulminant illness can develop in immunologically immature children or immunocompromised adults. However, in more than 95% of patients, the illness is mild and symptoms resolve in 4 to 6 weeks. If untreated, hosts then enter an indeterminate phase. Ten percent to 30% of patients progress from the indeterminate asymptomatic phase to a chronic symptomatic phase associated with cardiac enlargement, apical aneurysms, mural thrombi, megaesophagus, or megacolon, appearing years to decades after infection.[48–51]

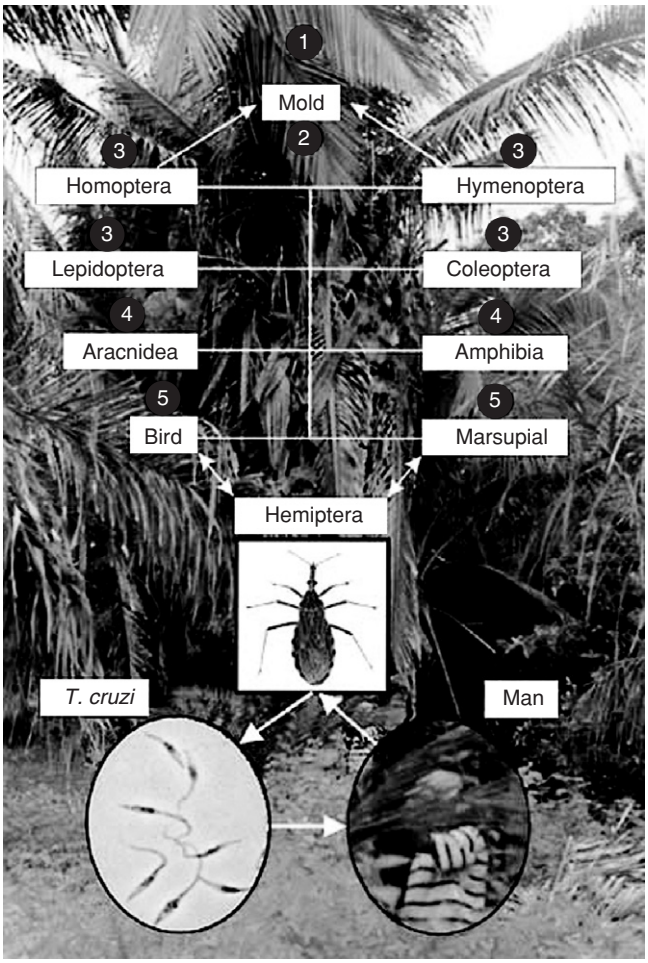

Figure 48–3 Triatomia bugs (Reduvidae), infected with *Trypanosoma cruzi*, reside in palm-tree frond clefts. Whereas birds are refractory to *T. cruzi* infections, marsupials and other residents of palm trees serve as reservoirs of infection. During the wet season when birds and mammals are scarce, triatomine bugs seek humans as a source of feeding, thereby spreading infection. (From Teixera ARL, Monteiro PS, Rebelo JM, et al. Emerging Chagas disease: Trophic network and cycle of transmission of *Trypanosoma cruzi* from palm trees in the Amazon. Emerg Infect Dis 2002;7:100–112).

Epidemiology

An estimated 16 to 18 million people are infected in South America, Central America, and Mexico, where Chagas disease is endemic and, historically, triatomid insects reside in cracks of rural and suburban houses with adobe walls. In the United States, an estimated 25,000 to 100,000 persons and 1 in 25,000 blood donors may be infected with *T. cruzi*.[48] Almost all are immigrants from Central and South America. Chagas disease is responsible for 50,000 deaths worldwide annually.[53]

Lifelong low-grade parasitemia persists in approximately 50% of those infected, and up to 63% of seropositive blood donors have parasitemia.[52] This presents a risk of transfusion transmission and of vertical transmission to infants. Between 12% and 48% of recipients of parasitemic blood become infected.

Transmission by Transfusion

Estimates of risk for transfusion-associated Chagas disease are related to immigration patterns from endemic regions. During the mid-1980s, 4.9% of 205 Nicaraguan and Salvadorian immigrants living in Washington, D.C., had serologic evidence of *T. cruzi* infection. Parasites were isolated from half.[54] In the early 1990s, 0.11% of a selected blood-donor population in California and the U.S. southwest was seropositive for *T. cruzi* antibodies. At least 50% of these donors were of Hispanic origin.[55] During the mid-1990s, 39.5% of donors at a hospital in Los Angeles responded affirmatively to questions inquiring about birth in Chagas disease–endemic areas or residing in dwellings constructed of palm leaf–thatched roofs or walls made of mud,[56] and 0.5% tested positive for *T. cruzi* antibodies. In a study conducted in the mid-to-late 1990s involving more than 1.1 million blood donors, 1 in 7500 in Los Angeles and 1 in 9000 in Miami were *T. cruzi* seropositive.[52]

Although a correlation exists between the percentage of immigrants from endemic areas and the percentage of blood donors with serologic evidence of *T. cruzi* infection, investigators have also identified seropositive blood donors who were born in the United States.[57] Congenital transmission may explain infection in these individuals. In addition, autochthonous transmission has been reported in the United States,[58] and an infestation of triatomines has been reported in Texas.[59]

Since 1989, seven cases of transfusion-associated Chagas disease have occurred in the United States and Canada.[61–65] Symptoms developed approximately 2 to 3 months after transfusion. In at least six of the cases, platelets were the implicated blood component; however, in the seventh case, the implicated unit was not identified.[63] Centrifugation may sediment *T. cruzi* into the platelet layer during component preparation, accounting for the association with platelet transfusions. Whereas room-temperature storage of platelets may favor parasite survival, *T. cruzi* has been shown to survive in refrigerated RBCs and whole blood for at least 18 to 21 days.[51] In six of the North American transfusion-associated cases, a donor emigrating from a *T. cruzi*–endemic region (Bolivia, Mexico, Paraguay, Chile) was identified. Four of the donors emigrated between 16 and 33 years before the implicated donation. Given this small number of cases, transfusion transmission of Chagas disease may be inefficient. In a study of 18 patients receiving blood from blood donors

subsequently found to be *T. cruzi* seropositive, none of the recipients became seropositive after transfusion. However, only two received platelet transfusions.[52] A report of Chagas disease also has been reported after transplantation involving an organ donor who emigrated from Central America appeared in 2002.[60] The recipient of a kidney and pancreas died of acute Chagas myocarditis 5 months after transplant. The recipients of the other kidney and the liver were both also infected with *T. cruzi.*

Transfusion Risk Reduction

Interventions to reduce the risk of transfusion-transmitted Chagas disease include questioning donors about geographic location of birth, extended stay or transfusion in areas endemic for Chagas disease, and serologic testing.[51,66,67] Donor history questions may be only 75% effective.[51] At least one candidate serologic screening assay has undergone clinical trials in the United States and is currently under review at the FDA. The U.S. FDA has indicated that it will require testing for Chagas disease if an appropriate screening assay achieves licensure. This decision reflects the reported transfusion- and organ transplant–associated cases and the concern that up to 600 transmissions may occur annually in the United States.[52] Leukocyte reduction by filtration is modestly effective, reducing *T. cruzii* transmission by 50% to 70% in a mouse transfusion model.[68]

SYPHILIS

Serologic testing of blood donations for syphilis was instituted in 1938 and required by regulation in 1958. No cases of transfusion-associated syphilis have occurred in the United States since 1966.[69] Multiple factors—improved donor selection, uniform serologic testing, lack of spirochete viability in blood stored at refrigerated temperatures, and widespread antibiotic use—apparently contribute to the current absence of transfusion-transmitted syphilis cases.[69-71] In 1978, the AABB Standards Committee deleted the requirement for syphilis testing, and an FDA advisory panel proposed eliminating the requirement for serologic syphilis testing in 1985. However, these changes were not made because of the belief that such testing might identify those at risk of transmitting the HIV. Subsequently, observational data did not support this assumption. Nonetheless, a National Institutes of Health Consensus Statement, issued in January 1995, recommended continuation of syphilis testing because its role in preventing transfusion-transmitted syphilis was not "understood."[70] A lack of complete laboratory data also supports test retention. Although spirochetes survive 96 to 120 hours at refrigerated temperatures,[72,73] viability at room temperature (e.g., in platelet concentrates) has not been studied. Furthermore, loss of viability during storage is an incomplete protection mechanism.

No single optimal laboratory test exists for syphilis. The infectious agent, *Treponema pallidum*, is an anaerobic organism that cannot be cultured in vitro.[73] During treponema infection, nontreponemal and treponemal antibodies are produced. The nontreponemal antibodies (reagin antibodies) react against phospholipid isolated from beef heart or cardiolipin. These antibodies are detected by the Venereal Disease Research Laboratory (VDRL), rapid plasma reagin (RPR), and other tests in response to the interaction of infected host tissue with *T. pallidum*. They parallel the pathologic course but have no relation to immunity. Treponema-specific antibodies have a higher serologic sensitivity in the early stages of syphilis but are less effective indicators of disease activity. During the first 3 weeks after primary infection, the VDRL is positive in 30% of cases, and the fluorescent treponemal antibody-absorption (FTA-ABS) test is positive in 50%. Other treponemal antibody tests, often used to confirm nontreponemal tests, include *T. pallidum* particle aggregation (TP-PA) and recombinant antigen tests. An automated test for treponemal antibodies, PK (TM) treponema pallidum (PK-TP), performed on the Olympus PK 7200, is widely used.[74–76] Reaction patterns characterized by positive RPR or PK-TP tests and negative FTA-ABS reactions (so-called false-positive reactions) may be caused by hepatitis, mononucleosis, viral pneumonia, chickenpox, measles, immunizations, pregnancy, or laboratory error. Persistent false-positive reactions have been reported in patients with rheumatoid arthritis, cirrhosis, ulcerative colitis, vasculitis, and older age.[74–76] Among PK-TP– and FTA-ABS–positive blood donors, approximately half give a prior history of a treated syphilis infection.[75] A history of lupus, rheumatoid arthritis, and diabetes did not provide an explanation for nonconfirmed PK-TP results.

The typical first sign of syphilis, a chancre, appears 3 to 90 days (average, 21 days) after exposure. The exact timing of spirochetemia and *T. pallidum* dissemination from the chancre and of seroconversion is not known. Secondary syphilis, characterized by a disseminated rash and spirochetemia, occurs 6 to 8 weeks after infection. Serologic tests are almost universally positive. If patients remain untreated, recurrent fulminant secondary syphilis recurs within 2 years in approximately 20%. Subsequently, patients become immune to reinfection and become noninfectious. VDRL titers decrease over time. Unless patients are treated in the primary stage, treponemal antibodies persist in both treated and untreated patients. Tertiary syphilis develops after a variable length of time. Reactivation is clinically and serologically noticeable via anticardiolipin and treponemal antibody detection.[72,74,76]

Currently, donations with reactive syphilis screening tests are unsuitable unless nonreactive in a confirmatory test. If the confirmatory test is positive, donors are deferred for 1 year; they are then allowed to donate again, provided that they have undergone adequate treatment for syphilis, and a nontreponemal assay is negative.[76]

HUMAN PARVOVIRUS

Clinical Findings and Epidemiology

Human parvovirus B19 was discovered serendipitously in human plasma during blood-donor screening for hepatitis B surface antigen in 1975. Initially, parvovirus was linked causally with transient aplastic crises in patients with sickle cell anemia and subsequently in patients with other inherited hemolytic diseases, as a result of severe reticulocytopenia and anemia. B19 was later found to be the etiologic agent of fifth disease or erythema infectiosum, a common childhood illness that manifests as an erythematous rash.[77,78] The rash occurs less often in infected adults than children. Fever and nonspecific symptoms precede the rash and arthralgia, both

of which probably result from immune complex deposition in the skin and other organs. Hepatitis, myocarditis, vasculitis, and the gloves-and-socks syndrome have also been linked to B19 infection (Fig. 48–4).

B19 infects only humans, and transmission occurs most commonly via the respiratory route. In addition, transplacental transmission of parvovirus B19 occurs in 30% of women infected during pregnancy. In women infected during weeks 9 to 20 of pregnancy, hydrops fetalis and fetal death occur in approximately 11%.[79] The virus is highly tropic for erythroid progenitor cells, gaining access to cells through the blood group P antigen, or globoside, which has been identified as the virus receptor.[77,78,80] The viral genome consists of single-stranded DNA that codes for three proteins. The nonstructural protein, NS1, is cytopathic to host cells. Viral protein 1 and viral protein 2 code for α-helical loops that appear on the capsid surface. Neutralizing antibodies recognize VP1. The nonenveloped virus consists of symmetric particles 25 mm in diameter.

B19 infection is ubiquitous in human populations and is already prevalent in pediatric age groups. Seroprevalence studies show antibody frequencies of 50% in high school–age children and up to 90% in older adults.[77,78] Epidemics and sporadic infections may occur at any time of year, with major outbreaks of erythema infectiosum occurring every 3 to 6 years. Persistent parvovirus infection, including pure RBC aplasia, occurs in those not developing neutralizing antibodies to VP1. The virus circulates at high titer, greater than 10^{12} genome copies per milliliter.[77,78] Patients receiving cytotoxic chemotherapy, immunosuppressive drugs, organ transplant recipients, and patients with immunodeficiency and the acquired immunodeficiency syndrome (AIDS) are at higher risk of developing chronic infections. The therapeutic approach for persistent parvovirus infection involves discontinuing immunosuppressive therapy, administering intravenous immunoglobulin (IVIG) preparations, instituting antiviral therapy for AIDS patients, and giving repeated courses of IVIG as needed.[77,78]

Transmission by Transfusion

The transient 1- to 2-week, high-titer viremia accompanying acute asymptomatic B19 infection allows virus transmission by blood, blood derivatives, and organ transplantation.[77,78,81] The infrequent recognition of transfusion-associated cases reflects the short viremic phase and the high frequency of immunity among transfusion recipients.

In contrast to recipients of blood transfusions, almost all recipients of plasma-derived factor VIII and IX concentrate are at risk for B19. Parvovirus circulates in the blood of approximately 1 in 800 plasma donors.[90] Fourteen percent had titers between 10^4 and 10^7 genome equivalents per milliliter, and 1 in 13,000 had greater than 10^7 genome equivalent per milliliter. Not surprisingly, in plasma derivatives

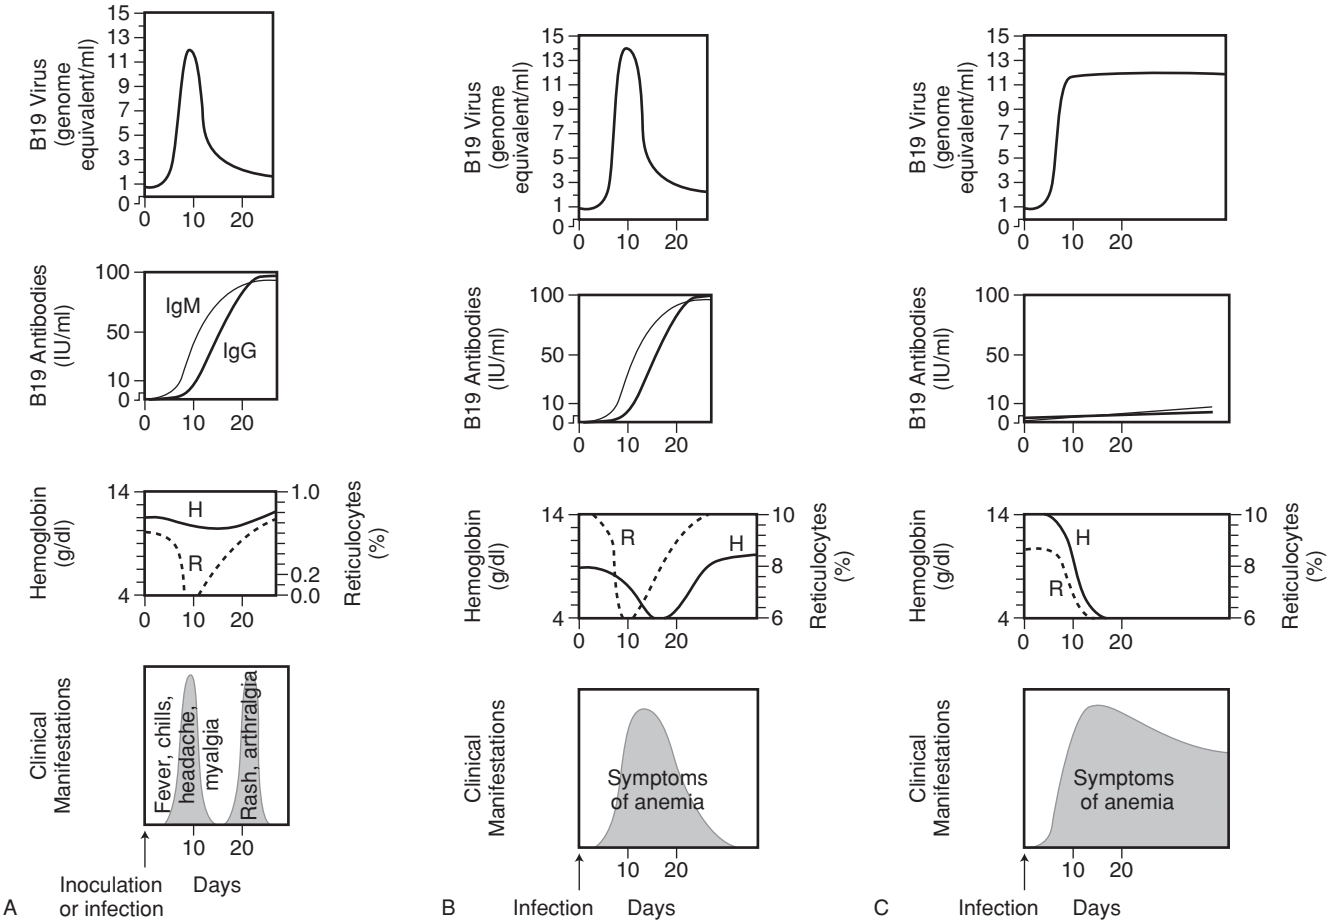

Figure 48–4 Parvovirus B19 infection: The viral titer progression, antibody response, hemoglobin and reticulocyte levels, and symptom complex vary among those with transient infections (**A**), patients with transient aplastic crisis (**B**), and patients developing red cell aplasia (persistent infection) (**C**). (From Young NS, Brown KE. Mechanisms of disease: Parvovirus B19. N Engl J Med 2004;350:586–597.)

prepared from large-scale plasma pools, PCR testing detects parvovirus B19 in most lots. In observational studies, recipients of solvent/detergent–treated plasma seroconverted after infusion of products with high-titer parvovirus DNA, $10^{7.5}$ to $10^{8.5}$ genome copies per milliliter, suggesting that the presence of anti-B19 antibodies was not protective against large viral loads. Seroconversion did not occur among recipients of lots with viral titers between $10^{0.5}$ and $10^{3.5}$ genome copies per milliliter.[78] The virus is resistant to viral-inactivation steps such as solvent/detergent treatment and heat after lyophilization or in the vapor stage. Heat may reduce infectivity if applied in the liquid state. Children receiving plasma-derived factor VIII concentrates were at least 1.9- to 7.6-fold more likely to be B19 seropositive than were those receiving no product or recombinant-derived anti-hemophilic factor.[87] Parvovirus seemingly becomes concentrated in the plasma fraction used in factor VIII preparations. Despite the high frequency of parvovirus exposure, long-term sequelae appear subtle.[82,87] For example, parvovirus B19–seropositive hemophilic children had an 8-degree loss in joint range of motion, a 0.48% difference, compared with seronegative children. Unlike factors VIII and IX, albumin has not transmitted parvovirus B19.[82–88] One report implicated parvovirus transmission by IVIG based on detection of viral DNA by PCR.[89] However, no documentation showed the same viral genotype in the recipient and the immunoglobulin preparation.

Measures to Reduce Transfusion Transmission

In light of these data, in 1999, regulatory agencies and manufacturers of plasma derivatives sought to reduce B19 DNA levels below 10^4 genome copies per milliliter in plasma pools containing 1000 to 3300 plasma donations. However, subsequent reports showed that parvovirus transmission occurred in a recipient of solvent/detergent–treated antihemophilic factor containing 1.3×10^3 genome equivalents per milliliter[83] and a recipient of a dry-heat–treated factor VIII product containing 4×10^3 genome equivalents per milliliter.[85] In these cases, smaller plasma batches with high viral loads were combined to form larger pools used in manufacturing the antihemophilic factor concentrates.

Currently, manufacturers conduct "in-process" testing to eliminate plasma donors with high-titer B19 levels. For example, "recovered plasma" (plasma obtained from whole-blood donations) that is intended for fractionation into plasma derivatives undergoes B19 DNA testing via nucleic acid amplification testing (NAT) assays on aliquots from pooled samples. Subpool analyses are performed to determine which of the samples contained the high-titer donor. These high-titer units, approximately 1 per 10,000 donations, are withheld from product manufacture. Because the infection is transient and a carrier states does not exist, the infected donor is not identified specifically or permanently deferred. Because whole-blood donations rarely transmit parvovirus infections, testing of single unit RBCs, platelets, or plasma for parvovirus B19 is not under consideration in the United States.

CREUTZFELDT-JAKOB DISEASE

Transmissible spongiform encephalopathies (TSEs) occurring in humans include kuru, CJD, Gerstmann-Sträussler-Scheinker disease (a phenotypic variant of CJD), fatal familial insomnia, and variant CJD (vCJD). TSEs occurring in animals include scrapie (sheep and goats), wasting disease of deer and elk, transmissible mink encephalopathy, and bovine spongiform encephalopathy.[91–93]

The TSE infectious agents are classified as prions, or proteinaceous infectious particles that lack nucleic acid. TSEs resist inactivating agents such as alcohol, formalin, ionizing and ultraviolet irradiation, proteases, and nucleases but are disrupted by autoclaving, phenols, detergents, and extremes in pH that affect proteins. The normal host membrane prion protein PrP (designated PrP^c), whose function is unknown, is protease sensitive, soluble, and has a high α-helix content. All prion diseases appear to involve conformational modification of PrP^c to a protease-resistant altered isoform that forms amyloid fibrils (designated PrP^{sc}). The conversion of PrP^c to PrP^{sc} results in refolding of a portion of the α-helical and coil structure of PrP^c into β-sheets. Neuronal loss and vacuolization leads to a spongioform appearance in the brain cortex and deep nuclei.

CJD occurs at an incidence of 0.5 to 1.5 cases per 1 million population worldwide. This rate has increased slightly over the past decade presumably on the basis of improved diagnostic accuracy and greater numbers of older individuals.[92,94] Fewer than 300 cases per year are reported in the United States. Sporadic CJD, causing approximately 85% of CJD cases, occurs in persons 40 to 80 years of age (average age at onset is 60 years) and is manifested by disordered sleep and decreased appetite, behavioral or cognitive changes or focal signs such as visual loss, cerebellar ataxia, asplasia, and motor deficits.[91] The mean survival time is 5 months. The mode of infection for sporadic CJD is uncertain. Approximately 10% to 15% of CJD cases occur in patients with a family history of CJD, suggesting an autosomal dominant inheritance pattern and mutations in the *PRMP* gene that codes for the prion protein. More than 50 mutations in this gene, located on the short arm of chromosome 20, have been identified, but 4 point mutations at codons 102, 178, 200, and 210 occur in 95% of familial cases.[91] Approximately 1% of CJD cases involve iatrogenic transmission. For example, CJD was transmitted by a corneal transplant from a patient with undiagnosed CJD, whereas stereotactic electroencephalographic silver electrodes previously implanted in a patient with CJD subsequently resulted in two iatrogenic CJD cases.[91,92] More than 130 young adults have died 5 to 30 years after receiving intramuscular human growth hormone injections prepared from cadaveric pituitary glands from donors with unsuspected CJD.[91,95] Cadaveric dura mater grafting with a commercial product prepared by batch processing resulted in at least 100 CJD cases worldwide, some occurring 18 years after graft placement.[91,96] In sporadic and iatrogenic cases of CJD, a polymorphism involving codon 129 in the PrP gene appears to affect susceptibility. Normally 37% of the population are methionine/methionine homozygous, and 11% are valine/valine homozygous at codon 129. The remaining 52% are heterozygous. Homozygous individuals represent almost 90% of sporadic and iatrogenic CJD cases.[96,100] Those homozygous for methionine are at risk for fatal familial insomnia, whereas those homozygous for valine are at risk of clinical CJD.[91]

In experiments involving mice infected with a strain of Gerstmann-Sträussler-Scheinker disease, blood-component infection was demonstrated.[97] In contrast, no evidence of transfusion-associated CJD was documented in case-control

studies involving more than 600 patients with CJD or in recipients of blood from persons who subsequently developed CJD.[98–100] Examination of brain tissue from deceased hemophilia patients showed no evidence of CJD.[91,101,102] No transfusion-associated CJD cases have been reported to date. Nonetheless, the occurrence of iatrogenic cases and the theoretical risk of CJD transmission by blood led the FDA to issue a recommendation to defer donors if they have one or more blood relatives with CJD or if they have received human pituitary–derived growth hormone injections or a dura mater transplant. All in-date products from donors with these risk factors must be quarantined and destroyed, and the previous recipients of blood from implicated donors, with the exception of those who have only one family member with CJD, must be notified.[92]

VARIANT CREUTZFELDT-JAKOB DISEASE

In the spring of 1985, several dairy cows in the United Kingdom displayed aggressive behavior, ataxia, and falling. These "mad cows" were found to have spongiform lesions in brain tissue resembling scrapie that was subsequently termed *bovine spongiform encephalopathy* (BSE). More than 180,000 cattle succumbed to BSE, but almost 1 million may have been infected. Because the mean incubation period for BSE is 5 years and most cows were slaughtered between 2 and 3 years of age, most cattle did not manifest disease.[91–93] Approximately 50,000 BSE-infected cattle entered the food chain before the first BSE case was recognized in 1986. Subsequently, the onset of the BSE epidemic was traced to a meat-and-bone cattle feed made from sheep, cattle, and pig offal. The rendering process presumably resulted in the feeding of scrapie-infected material to cows. Use of sheep offal or other tissues from ruminant animals as feed for other ruminant animals was banned in 1989. The annual incidence of clinical cases in cattle peaked in 1992. After March 1996, only animals younger than 30 months were eligible for food preparation.[93]

Surveillance for human CJD cases heightened in the United Kingdom after recognition of the BSE epidemic. Ten of 207 CJD patients in 1994 and 1995 had unusual neuropathologic changes.[103,104] They had predominantly psychiatric and sensory symptoms, ataxia, dementia, and myoclonus. All were younger than 45 years, a distinctly unusual characteristic for CJD. Electroencephalographic features were not typical of CJD, and florid PrP plaques were seen on neuropathologic examination. Median survival time was 14 months, in contrast to 4 months for CJD. These cases were considered a new variant of CJD (vCJD). The median incubation period for food-borne vCJD is 13 years.[105] Extensive investigations using animal models provided evidence that the same prion strain causes BSE and vCJD.[106] Ingestion of British beef, therefore, was identified as a risk factor for BSE.[107]

As of June 2006, 159 cases of vCJD have been reported in the United Kingdom, 17 in France, 4 in Ireland, 1 each in Portugal, Spain, Italy, the Netherlands, Saudi Arabia, Japan, and Canada, and 2 in the United States. The latter three plus one Irish patient were thought to result from exposure in the United Kingdom. The Japanese patient spent only 24 days in the United Kingdom. All patients tested were homozygous for methionine at PrP codon 129. By 2000, the incidence of human vCJD cases peaked, suggesting that clinical manifestations among methionine/methionine homozygotes may be less than anticipated after extensive exposure to cattle with subclinical disease.[105,108,109]

Concern about transfusion transmission of vCJD increased because PrP^{sc} is found consistently in the lymphoreticular system of vCJD patients, the possibility that circulating prions transfer the infection from the gut to the brain, and eventually because of animal studies.[105,108,109] In animal model experiments, sheep were fed aliquots of brain obtained from BSE-infected cattle. Subsequently, the sheep underwent phlebotomy at periodic intervals. Among 24 sheep receiving blood from iatrogenically infected donor sheep, 2 given blood from donors in the preclinical BSE phase developed BSE, and 2 receiving blood from clinically affected sheep showed clinical signs of BSE. Among 21 sheep transfused with blood from natural scrapie-infected animals, 4 demonstrated clinical signs of scrapie.[110,111]

An active investigation to determine whether transfusion associated-vCJD transmission occurs in humans began in the United Kingdom in 1997 by identifying vCJD patients who donated blood before illness. Eventually, 48 recipients of blood from 15 donors with vCJD were identified. Three of the 48 recipients, to date, have evidence of vCJD. One, at age 62 years, received non–leukocyte-reduced RBCs from a 24-year-old donor who developed vCJD 3.5 years after the blood donation. The transfusion recipient developed vCJD 6.5 years after transfusion.[112] The second patient received a transfusion of non–leukocyte-reduced RBCs in 1999.[113] The donor developed vCJD 18 months later. The asymptomatic recipient died of a ruptured abdominal aortic aneurysm 5 years after transfusion. At autopsy, protease-resistant prions were present in the spleen and cervical lymph nodes. Prions were not detected in the brain. The recipient, found to be heterozygous (methionine/valine at codon 129), did not have clinical vCJD, raising concern that the incubation period may be longer in codon 129 heterozygotes. In animal studies, a primary challenge with vCJD prions resulted in a significantly reduced transmission rate in mice with valine at codon 129 compared with that in animals homozygous for methionine.[114] Additional data are needed to confirm whether the incubation period varies among methionine homozygous and heterozygous individuals. The third case developed vCJD approximately 8 years after receiving non-leukocyte-reduced red cells from a person who developed vCJD 20 months postdonation.[114a]

The U.K. National Blood Service also determined that approximately 100 people donated blood to four patients who subsequently showed clinical signs of vCJD. These donors were notified that they may be at higher risk of developing vCJD despite the uncertainty of whether the patients contracted vCJD through food or blood transfusion. In addition, UK authorities notified recipients of factor XI concentrates that donors of these components developed vCJD after donation on the ethical tenet of transparency. The United Kingdom currently imports plasma from the United States for patients younger than 16 years and uses apheresis-derived platelets in these patients to reduce donor exposures.[94,116]

The identification of presumed transfusion-associated vCJD cases appears to validate the steps taken in response to the precautionary principle to decrease the risk of transmitting vCJD by transfusion.[92] Donors who visited or resided in the United Kingdom for a cumulative period of 3 months or longer between 1980 and 1996 are deferred indefinitely. Donors who spent 5 years or more in Europe before 1980 and the present are also deferred. In addition, donors are indefinitely deferred if they injected bovine insulin after 1980, received transfusions in the United Kingdom and France

between 1980 and the present, or served in the military on bases in Europe for 6 months or more between 1980 and 1996. This geography-based donor-deferral protocol evolved in various phases beginning in 1999. Approximately 3.5% of potential donors in the United States have been deferred as a result of this policy.[117] The impact was higher in Canada.[118] In-date blood components and plasma intended for derivative production from these donors must be recalled, quarantined, and destroyed. Ongoing surveillance of vCJD cases, which increased after identification of a Texas cow with BSE, is currently being conducted, including a recommendation to notify the CDC about all patients younger than 55 years who are diagnosed with CJD.[115]

In addition to geographic exclusion policies, other strategies for preventing vCJD transmission include removal of the infectious agent and testing. In the United Kingdom, all blood components undergo leukocyte reduction by filtration, based on observations that prions associate with leukocytes. Leukocyte reduction, however, is only partially effective, removing only 42% of total prion infectivity.[120] Filters that specifically remove prions and laboratory tests that detect infectious prions are currently being developed and evaluated. The latter, if implemented, will be accompanied by significant ethical concerns.[119]

LEISHMANIASIS

Visceral forms of leishmaniasis result from infection with *Leishmania donovani* or *Leishmania infantum.* Cutaneous lesions occur in persons infected with *Leishmania braziliensis* or *Leishmania tropica*, the cause of Old World cutaneous leishmaniasis. However, at least eight soldiers returning from eastern Saudi Arabia after Operation Desert Storm developed visceral leishmaniasis that was attributed to *L. tropica.*[121,122]

The leishmania organisms, transmitted primarily by bites from infected sand flies, are endemic in the tropical and subtropical regions of the Sudan, Eastern India, Bangladesh, Nepal, Brazil, and the Mediterranean.[123]

After transmission by sand fly bite, parasites reside intracellularly in monocytes, which circulate before taking up residence in internal organs. In the most severe manifestation of visceral leishmaniasis, kala-azar, patients have marked hepatosplenomegaly, pancytopenia, hypergammaglobulinemia, and cachexia. The incubation period is approximately 6 months.[123] Anti–*L. donovani* antibodies form shortly after infection. In studies conducted in Brazil, 21 seropositive asymptomatic blood donors were found to have positive PCR results for *L. donovani*, demonstrating the ongoing potential of transfusion transmission in endemic areas.[124]

At least 10 transfusion-associated cases of leishmaniasis attributed to *L. donovani* have been reported in endemic regions. Most of those infected were young children or neonates. A probable case of platelet transfusion–transmitted *Leishmania* was reported recently.[125] Transfusion-transmission also appears to occur in dogs receiving transfusions of RBCs from seropositive dog-blood donors.[126]

Veterans of Operation Desert Storm who served in the Persian Gulf region between August 1990 and December 1992 were deferred from blood donation for 1 year, after the report of *L. tropica*–related viscerotropic leishmaniasis. The patients had nonspecific clinical manifestations, including prolonged fever, malaise, abdominal pain, and intermittent diarrhea, which occurred up to 7 months after they returned to the United States.[121] *L. tropica* was found in the bone marrow of seven patients and in a lymph node in one patient. Intracellular amastigotes were seen in the peripheral blood of the one patient in whom this was studied.[127] After reports of hundreds of cases of cutaneous leishmaniasis and two cases of visceral leishmaniasis in troops involved in the Iraq war, a similar 1-year deferral after departure from Iraq was instituted in October 2003.[127] *L. tropica* within human monocytes survives in blood stored at 1° C to 6° C, in frozen RBCs, and in platelet concentrates stored at room temperature. However, *L. tropica* has not been detected in relatively cell-free fresh frozen plasma. Animal studies demonstrate transmission by contaminated blood.[126]

No cases of transfusion-transmitted leishmaniasis have been reported in the United States to date. For this reason, surveillance and targeted donor deferral appear to be appropriate. Use of leukocyte filters to reduce *Leishmania* transmission is under investigation.[128]

TOXOPLASMOSIS

Toxoplasma gondii is a ubiquitous parasite whose usual host is the domestic cat. Infection sometimes results in lymphadenopathy, malaise, fever, headache, sore throat, splenomegaly, hepatomegaly, and rash. Retinopathy and lethal infections occur in immunocompromised hosts.

Transfusion transmission was reported in 1971. However, the cases occurred among leukemia patients given granulocyte transfusions obtained from other leukemic patients. Another case report suggested that a patient undergoing chemotherapy for a leukemic relapse 3 years after receiving an allogeneic marrow transplant developed toxoplasma pneumonitis. A person with serologic evidence of recent toxoplasma infection donated one of the units of blood transfused to the patient.[130] In addition, a 52-year-old woman with drug-induced thrombocytopenia developed toxoplasma retinochoroiditis, presumably related to a platelet transfusion.[130] A case further emphasizing the importance of nontraditional routes of infection in immunocompromised patients involved a renal transplant recipient who developed toxoplasmosis.[131] The infection was presumably transmitted by a kidney obtained from a seropositive organ donor.

DENGUE

Dengue, transmitted by *Aedes* mosquitoes, has infected at least 77 U.S. travelers to Caribbean islands (including Puerto Rico and the U.S. Virgin Islands), Pacific islands, Asia, Central America, Africa, and Hawaii between 2001 and 2004.[132,133] The incubation period is 3 to 14 days. Infections cause either no symptoms, mild illness, or severe disease including hemorrhagic manifestations and shock.[134] Transmission by bone marrow transplantation and several reports of transmission after needle-stick injuries involving symptomatic patients raise the possibility of transfusion transmission by asymptomatic travelers returning from endemic areas.[135–137]

SIMIAN FOAMY VIRUS

More than 70% of nonhuman primates in zoos or in animal research facilities are infected with simian foamy virus (SFV),

an endogenous, cell-associated retrovirus found in New and Old World primates.[138] Surveillance studies indicate that approximately 5% of zoo and biomedical research personnel working with chimpanzees and baboons are infected with SFV. Evaluation of archival samples documented infection for 8 to 26 years (median, 22 years). All subjects remained healthy, and each of three spouses undergoing testing for SFV were nonreactive. In addition, 1% of bush hunters in central Africa and 1% of those exposed to free-ranging nonhuman primates in Asia tested positive for SFV.[139,140] Presumably, those infected were inoculated through exposure to saliva from bites or close contact through exposure to body fluids.

Only limited information is available about transfusion transmission. One occupationally exposed SFV-infected individual donated blood 6 times during an interval when SFV test results, conducted retrospectively, were positive. None of the tested recipients of RBCs, leukocyte-reduced RBCs, or platelets was SFV positive. Three of these blood components were stored for less than 8 days.[141]

LYMPHOCYTIC CHORIOMENINGITIS VIRUS

Infections with lymphocytic choriomenigitis virus (LCMV), a rodent-borne arenavirus, usually cause mild, self-limited illness or aseptic meningitis in nonimmunosuppressed patients. Human infections typically follow exposures to body fluids or infected animal excretions. Vertical transmission occurs, but LCMV is not considered to be communicable from person to person. LCMV has been transmitted to four organ transplant recipients via an asymptomatic organ donor who had a cerebrovascular accident and subsequent brain death.[142] The donor apparently became infected by exposure to a pet hamster. Within 3 weeks of transplantation, the recipients of the liver, lungs, and two kidneys developed fever, rash, or diarrhea; three of the four recipients died. A previous case also involving four transplant recipients was unrecognized until this case was reported. Transfusion transmission has not been reported but is a possibility, given transmission by solid-organ transplantation.

H5N1 AVIAN INFLUENZA VIRUS

The avian influenza A/H5N1 virus has spread epidemically among birds and poultry since emerging in Hong Kong in 1997.[143] Since that time, more than 100 million birds and poultry have died or been culled to prevent epidemic progression via bird migration in Cambodia, China, Indonesia, Japan, Laos, South Korea, Thailand, Vietnam, Malaysia, Turkey, Romania, and Russia. Transmission to humans via contact with infected poultry or contaminated surfaces has resulted in more than 60 deaths.

To date, human-to-human transmission has occurred infrequently.[144] However, concern exists that mutations, reassortments, or recombinant rearrangements of the virus with pathogenic human influenza viruses could produce a virus capable of jumping the species barrier and causing a worldwide pandemic. Influenza viremia is infrequent, although highly pathogenic avian influenza can be transmitted via blood.[145] Although transfusion transmission is a theoretical risk, a more likely impact would be large-scale donor illness and blood shortages.

SEVERE ACUTE RESPIRATORY SYNDROME

SARS, caused by a novel enveloped RNA coronavirus, infected more than 1800 patients in 17 countries in February and March 2003.[146] This highly contagious illness dominated worldwide public health attention, resulting in rapid identification, travel advisories, patient quarantine, and eventual eradication of the epidemic.[147] The 2-week asymptomatic incubation period fostered spread of the virus through close person-to-person contact and raised the possibility of blood-borne infection. For this reason, the U.S. FDA issued a guidance document in April 2003 requiring blood-collection agencies to defer anyone from donating blood for at least 14 days after possible exposure to SARS.[148] Those with a suspected SARS illness were deferred for at least 28 days after recovery. Notices were posted in blood centers apprising donors about SARS-affected areas, and donors were asked about recent travel history. Those traveling to affected areas, including transit in an airport at these locations, were deferred from blood donation. The epidemic subsided within months. No reports of transfusion-associated SARS exist.

WEST NILE VIRUS

West Nile Virus (WNV) is a mosquito-borne, lipid-enveloped, RNA virus in the Japanese encephalitis flaviridae complex. The viral genome codes for capsid, membrane, envelope, and nonstructural proteins.[149]

The virus, transmitted from bird to bird by mosquito vectors, infects humans as incidental hosts. The virus was identified in the West Nile district of Uganda in 1937. Outbreaks occurred subsequently in the Mid-East, South Africa, and Europe. The first North American cases were recorded in New York City in 1999.[150–153] WNV infections in humans have occurred predominantly between June through October, peaking in August through late September and remitting during the winter. Starting in July 2000, WNV cases were reported in Mid-Atlantic states. In July 2001, 66 cases occurred in the eastern one third of the United States. In 2002 the epidemic spread to the Midwest and eastern Plains states; 4156 cases were reported including 2946 with meningoencephalitis. In 2003, further western spread saw the majority of cases in the Plains states of Nebraska, Colorado, North and South Dakota, and Wyoming; 9862 cases were reported, including 2775 with neuroinvasive complications. In 2004, the epidemic spread farther westward to include Arizona and southern California. WNV activity was reported in 47 states, involving 2470 reports. WNV cases in 2005 progressed farther down the West Coast; 2435 cases were reported through October 2005.[154] In addition, 372 viremic blood donors were identified.

WNV activity in birds and mosquitos occurs throughout the year, especially in warmer regions. The virus becomes detectable in blood 1 to 3 days after a mosquito bite, followed by an increase in viral loads. However, peak titers are relatively low (median of 3500 copies per milliliter) compared with HIV and HCV (10^5 to 10^7 per milliliter). RNA levels decrease markedly 7 to 10 days after infection when immunoglobulin M (IgM) antibodies, and subsequently IgG anitibodies, appear. IgM antibodies persist for more than 398 days in approximately two thirds of those infected.[155] The mean duration of viremia is 6 days. However, WNV RNA

was detected up to 104 days after infection in one blood donor.[157–162] (Fig. 48–5)

Approximately 80% of persons infected with WNV remain asymptomatic. The 20% with symptomatic infections report abdominal pain, chills, fever, generalized weakness, headache, joint pain, muscle weakness and pain, new macular rash on the trunk and extremities, new difficulty thinking, painful eyes, and swollen glands.[163] One in 150 infected persons develops meningitis, encephalitis, or asymmetric flaccid paralysis. Fatal outcomes occur in 4% to 14% of those with severe disease.

WNV transmission in four recipients of organ donations was reported in 2002.[163] The organ donor, in turn, received blood transfusions from 63 donors, one of whom subsequently was found to be WNV infected. A sample from the organ donor subsequently tested WNV RNA positive, but WNV IgM negative. Initial reports of transmission by blood transfusion in 2002 eventually resulted in confirmation of 23 cases of transfusion-associated WNV infection.[162] The interval between transfusion and symptom onset was 10 days (median interval range, 2 to 21 days). Nine of 14 implicated blood donors reported WNV-associated symptoms before donation.

After intense collaboration among U.S. public health authorities, test manufacturers, and blood-collection agencies, NAT for WNV RNA was implemented before the 2003 WNV season. As a direct result of testing, more than 1000 donors were found to be WNV RNA positive in 2003, preventing WNV transmission to approximately 1500 recipients of RBCs and components prepared from these donations.[156,157,159] During the summer months, approximately 1 per 7000 units was WNV RNA positive. In high WNV endemic areas, 1 in approximately 150 donors was WNV viremic. In 2003, six transfusion-associated WNV cases were reported.[158] All of the implicated donors had extremely low-level viremia that escaped detection by routine testing in minipools containing aliquots from 6 to 16 donations. Testing of individual samples in high-incidence areas increases test sensitivity by approximately 7% and was introduced in 2004 when incident cases exceeded preestablished thresholds (approximately 1 WNV-positive donor per 1000 donations). Only one confirmed transmission occurred in 2004. Among the 30 confirmed transfusion cases, all implicated donations were WNV IgM antibody negative.[164,165]

A second transplant-associated incident involving three of four organ recipients who developed WNV infection after transplant was reported in 2005.[166] Of note, the organ donor (infected through mosquito bites) was WNV RNA positive and IgM antibody positive. This report raises concern that organ-transplant recipients and other heavily immunosuppressed patients are at extremely high risk for severe WNV complications and that the virus remains viable in organ/tissue reservoirs despite a humoral immune response.

Overall, the rapid implementation of WNV testing within months of the initial transplant and transfusion-associated cases resulted in dramatic reduction of further transfusion-transmitted cases. Assuming that RNA-positive, IgM antibody–positive donors do not transmit WNV through blood transfusion, the residual risk of transfusion-associated WNV after implementation of NAT is approximately 1 per 350,000 donations.[164,165]

RABIES

In June 2004, the CDC confirmed the diagnosis of rabies in recipients of a liver and two kidneys from an organ donor subsequently found infected with rabies via a bat bite. The recipients developed tremors, myoclonic jerks, altered mental status, or anorexia 21 to 27 days after transplant. All died. It is unlikely that these transplant-related cases portend a risk for transfusion-transmission, in that exposure to infected neuronal tissue appears to be the vector in these cases. The rabies virus is not transmitted hematologically, and contact with blood, urine or feces is not considered an exposure risk.[167]

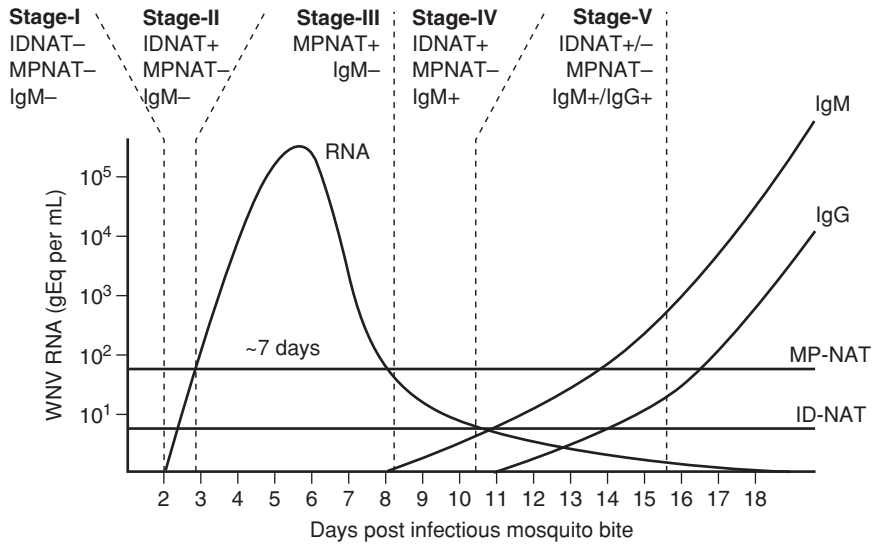

Figure 48–5 West Nile virus (WNV) RNA circulates at relatively low levels for 7 to 10 days after the bite of an infected mosquito. Minipool nucleic acid testing (MP-NAT) detects 43 to 309 viral copies per milliliter within a few days of infection. In contrast, individual donation NAT (ID-NAT) detects 3.4 to 29 copies per milliliter and reduces the window period between infection and test detection. All transfusion-associated WNV cases have occurred in the NAT-positive/IgM antibody–negative stages. (From Busch MP. West Nile virus window period. Transfusion 2005;45:cover figure.)

Chapter 49

Hemolytic Transfusion Reactions: Acute and Delayed

R. Sue Shirey • Karen E. King • Paul M. Ness

ACUTE HEMOLYTIC TRANSFUSION REACTIONS

The most feared adverse reaction to blood transfusion is an acute hemolytic transfusion reaction (AHTR). These reactions most commonly occur when red cells (RBCs) are transfused to a patient with a preexisting antibody that is capable of destroying incompatible RBCs through intravascular hemolysis. These reactions can produce hypotension and shock, often accompanied by acute renal failure and disseminated intravascular coagulation (DIC), and have a high mortality rate. Because of the devastating nature of the most severe cases of AHTR, blood centers and transfusion services have developed standard operating procedures to avoid these consequences. Clinicians are taught to be suspicious of AHTRs and to initiate treatment rapidly in the hope of preventing the many complications and sequelae.

Definition and Incidence

An AHTR features rapid destruction of RBCs immediately after a transfusion, but a hemolytic reaction occurring within 24 hours of the inciting transfusion is generally considered to be an AHTR.[1] AHTRs produce serologic abnormalities and clinical events, but most reports do not distinguish how the cases were identified, and the literature has not developed a consensus case definition. Most reported reactions occur with RBCs, but AHTR reactions due to RBC antibodies contained in the plasma of other blood components (platelets or plasma-derived products) have historically and more recently been recognized as producing AHTRs.[2]

The incidence of AHTR in clinical practice has never been precisely determined. Historic studies have estimated their occurrence to be from 1 in 10,000 to 1 in 50,000 transfused blood components.[3,4] Other information has been gleaned from reports to the Food and Drug Administration (FDA) on transfusion fatalities, but these numbers clearly misrepresent the totality of AHTR reactions.[5,6] Any transfusion-medicine veteran knows of many cases or near misses from quality assurance activities or medical/legal cases that are never reported. The growing use of hemovigilance reporting around the world may provide better data in the future. As an example, a report from Canada documented 11 cases of AHTR from 138,605 units of RBC administered in 2000.[7] Because these reactions occurred in hospitals where transfusion safety officers were already in place, it is likely that the incidence is higher in sites where hemovigilance activities have not been initiated.

It is logical that reaction severity will correlate with the amount of incompatible blood that is administered. Published reports document death rates of 25% when less than 1 L of RBCs was given, with mortality increasing to 44% when infusions of greater than 1 L were transfused.[8] Conversely, small aliquots of blood have caused major reactions,[6] and whole units of RBCs that were ABO incompatible caused no sequelae.

Pathophysiology

Transfusion of RBCs that are incompatible with antibodies in the patient's plasma most commonly initiates AHTR. Less commonly, antibodies can be transfused from the donor that will destroy the patient's incompatible RBCs. The antibodies that cause AHTR are most commonly within the ABO system, where high-titer naturally occurring antibodies react with the dense ABO antigen sites on RBCs, producing hemolysis. Anti-A is the most common culprit, because it has a higher titer in most group O individuals, and transfusion errors involving administration of group A blood to group O individuals are statistically most probable. Although ABO antibodies account for the majority of fatal cases of AHTR, other antibodies in the Kell, Rh, Kidd, and Duffy systems can be equally severe in some cases.[3]

The initiating events of an AHTR involve the binding of antibody to incompatible RBCs and the subsequent destruction of the RBCs by intravascular hemolysis. These events activate the complement system, the release of hemoglobin from the RBCs, and the presence of residual RBC stroma in the circulation. Although AHTR is typically considered a classic example of intravascular hemolysis, most likely some elements of extravascular hemolysis occur as well with clearance of some damaged red cells by the reticuloendothelial system.

Immune hemolysis with complement activation generates the major complications of AHTR through a series of activated complement components, anaphylotoxins, and other immune mediators such as cytokines and vasoactive amines.[1] These events cause hypotension, vasoconstriction and renal ischemia, and the activation of the coagulation

system of platelets and clotting factors. When complement is fully activated and RBC stroma and enzymes are released into the vascular space, hypotension results from the actions of anaphylotoxins and mast cell degranulation, with release of histamine and serotonin. Hypotension and renal failure are also facilitated by the activity of cytokines and interleukins produced as a result of immune hemolysis.[9] The kallikrein system and bradykinin are also activated, causing vasodilation with increased capillary permeability, adding to the clinical picture of shock with renal failure, along with elements of adult respiratory distress syndrome.[10] The massive release of proinflammatory molecules such as tumor necrosis factor (TNF)-α, interleukin (IL)-1, and IL-8 activate neutrophils and monocytes, enhancing the clinical picture of shock, renal failure, and pulmonary compromise.[11,12]

These catastrophic events have profound effects on platelets and the coagulation system as well. Platelets are activated by the immune hemolytic reaction, releasing additional serotonin and histamine, which furthers the vasoconstrictive events. Platelet phospholipid (platelet factor 3) is also released, with procoagulant effects on coagulation.[13,14] As a result, the intrinsic coagulation system is activated with the presence of bioactive thrombin, the consumption of fibrinogen, and the initiation of fibrinolysis. These procoagulant forces produce microthrombi, exacerbating renal damage, and diminished platelets and coagulation factors in many patients produce the clinical picture of DIC and hemostatic compromise.

Most of the evolving picture of the pathophysiology of AHTR has been extracted from clinical case reports and descriptions. Much of this picture was well described in an early review by Goldfinger[15] in 1977. This seminal review was updated with a more comprehensive picture of the implications of the systemic inflammatory response in AHTR later by Capon and Goldfinger[16] formulating a model for the consideration of therapy. The pathophysiology of AHTR has also been studied in animals in recent years by Davenport,[12,13] with the identification of important clinical roles of immune mediators such as IL-1 and monocyte chemoattractant protein. We hope that animal models will provide insights into potential therapies because clinical trials of newer agents will be difficult to perform in the sporadic cases that occur in multiple locations.

Clinical Picture

No consistent clinical picture of AHTR exists, with reactions being described in all settings where transfusion therapy is being administered. Most commonly, an alert patient might complain of chills, and the vital signs that are monitored with transfusion therapy will detect hypotension and fever. Pain at the infusion site, flank pain, a general feeling of being unwell, and anxiety with a feeling of impending doom have also been described. In patients who are unconscious or in surgery, vital-sign changes and the onset of unexplained bleeding due to DIC or the observation of hemoglobinuria in catheterized patients may be the only warning. Because the presentation of AHTR is nonspecific, it is critical that all patients undergoing transfusion therapy be closely observed with careful monitoring of vital signs and that any untoward complication be evaluated immediately as a suspected transfusion reaction. A list of common signs and symptoms of AHTR is found in Table 49–1, although the list is by no means exhaustive.

Table 49–1 Signs and Symptoms of Acute Hemolytic Transfusion Reactions

Fever	Nausea and vomiting
Chills	Dyspnea
Rigors	Hypotension
Anxiety, feeling of doom	Hemoglobinuria
Facial flushing	Oliguria/anuria
Chest and abdominal pain	Pain at the infusion site
Flank and back pain	Diffuse bleeding

Differential Diagnosis

Because patients receiving transfusion therapy can develop a clinical picture of hemolysis from many sources, it is important to distinguish an AHTR from acute hemolysis of other causes. Probably the most common cause of hemolysis in transfused patients is the improper storage of RBCs, leading to hemolysis of the unit; these events can occur if the blood is affected by thermal injury, subjected to mechanical trauma from constricted access lines or pressurized infusions, inappropriately mixed with hypotonic solutions or drugs, or contaminated by bacteria. These forms of nonimmune hemolysis can be avoided by careful attention to routinely available transfusion protocols for the storage and administration of blood components.

Some patients with congenital or acquired forms of hemolytic anemia may be incorrectly assumed to have had an AHTR. Acute hemolysis in congenital hemolytic anemias such as hereditary spherocytosis, sickle cell anemia, or RBC enzyme deficiency states can occasionally be misidentified as an AHTR. Other conditions in critically ill patients can confuse transfusing clinicians, such as a coexistent microangiopathic hemolytic anemia, a patient with thrombotic thrombocytopenic purpura (TTP)/hemolytic-uremic syndrome (HUS), or patients with mechanical fragmentation of RBCs due to heart valves or other implanted circulatory devices.

Confirmation of the Diagnosis

The initial suspicion of an AHTR should prompt discontinuation of the ongoing transfusion and an initial laboratory investigation (Table 49–2) including observation of the post-transfusion plasma for hemolysis and the performance of a direct antiglobulin test. Visual inspection of the plasma is subject to many causes of false-positive results, including the enumerated sources of nonimmune hemolysis, the presence of another hemolytic state, or an improperly drawn blood sample. The direct antiglobulin test also is subject to false-positive results. If either of these screening tests is positive, however, particularly in the presence of a compelling clinical story, further testing should be initiated in the transfusion service. Administration sets and blood bags should be examined, and the pretransfusion testing of the patient should be repeated. It is critically important in these cases to affirm the identity of the patient, to assure that the pretransfusion specimen was actually from the patient who encountered the reaction, to affirm that other patients are not involved in an identification error, and to withhold further transfusions unless urgently required until the presence or absence of an AHTR has been confirmed.

Table 49–2 Laboratory Investigations for Acute Hemolytic Transfusion Reactions

Blood product	Confirm ABO, Rh
	Confirm other antigen types, if indicated
Blood bank laboratory	Direct antiglobulin test
	Confirm ABO, Rh, antibody screen and identification
	Post-transfusion hemolysis check
Clinical laboratory	Complete blood count
	Platelet count
	Urinalysis for hemoglobin
	Serum bilirubin
	Creatinine, urine quantitation
	Coagulation profile
	DIC evaluation

DIC, disseminated intravascular coagulation.

The treating physician may want to order additional laboratory tests to confirm the clinical suspicion of an AHTR or to provide additional tests to facilitate therapy and monitor the patient's status. These tests might include a complete blood count including platelets, coagulation screening, serum chemistries including creatinine, and tests to confirm hemolysis, such as haptoglobin, lactic dehydrogenase, and bilirubin. In complicated cases, a visual inspection of the post-transfusion blood smear also can be helpful.

The laboratory may also be required to perform a more definitive evaluation for DIC in confirmed cases.

Therapy

The first element of therapy of an AHTR is to stop the infusion of the suspected incompatible blood.[16] It also is critical to maintain intravenous access for the patient, so the intravenous line should not be removed or sent to the laboratory for evaluation. In a suspected reaction, emergency measures may precede definitive confirmation. The early management should include careful monitoring of the vital signs, maintenance of the blood pressure and blood volume, and transfer of the patient to the appropriate acute care setting (most likely an intensive care unit [ICU]) for aggressive management, if required (Table 49–3). An intensive care specialist or a nephrologist or both should be consulted because dialysis therapy may be required. If AHTR due to ABO compatibility is confirmed, a pulmonary artery catheter may be critical for monitoring. Aggressive fluid replacement is subsequently administered, and vasopressors, such as dopamine, are commonly used in an attempt to mitigate renal complications. Diuretics such as furosemide are commonly administered to maintain urine output along with fluid support.[17] If renal failure ensues, however, dialysis should be initiated promptly.

In the event that bleeding ensues or the laboratory confirms that DIC has developed, supportive therapy with platelet concentrates and plasma products may become important. The use of heparin has been advocated to prevent or reduce the complications of DIC but may be difficult in the face of surgical bleeding.[18] The use of protein C concentrates to interrupt DIC should also be considered, although clinical trial support is obviously lacking.[19]

The classic clinical descriptions of AHTR did not include the respiratory failure that can occur and is now more commonly recognized. Pulmonary function should be carefully monitored, with oxygen therapy and ventilator support initiated early by the intensive care specialists. Whether specific inflammatory inhibitors that have been studied for other chronic inflammatory states (inhibitors of IL-1 or TNF) would be useful is not known, but their use in severe situations appears justifiable.

PREVENTION

The basic procedures used by blood banks for pretransfusion testing and management of transfusion practices are designed to eliminate AHTR. The most important cornerstone is the proper identification of the blood recipient and the collection of a carefully identified blood sample from the recipient for pretransfusion testing. Blood banking procedures are often deemed to be unnecessarily rigid by clinicians, but they must be enforced to lessen AHTR and other preventable transfusion consequences. The most effective systems require identification of the patient at the bedside and creating a unique identifier based on the personal identification by the phlebotomist. Barrier systems also prevent transfusion without the precise identification of the recipient.[20] Computer technology is being adapted to make sample and recipient matching more rigorous in the hope of preventing transfusion errors and transfusion reactions.[21] Another trend that should reduce transfusion reactions such as AHTR is the development of quality assurance systems (hemovigilance) that monitor transfusion practices, investigate transfusion reactions, reinforce training of physicians and nurses about transfusion care, and help to develop improved systems in hospitals to lessen transfusion risks.

Once a sample is obtained in the blood bank, blood bank procedures are designed to detect ABO discrepancies and alloantibodies that can cause immune hemolysis and AHTR. Procedures are designed to be very sensitive so that antibodies will not be missed, but some highly sensitive procedures produce a problem with a high incidence of false-positive

Table 49–3 Therapy for Acute Hemolytic Transfusion Reactions

General Considerations	Prevent Renal Complications	Pulmonary Complications	Management of DIC
Establish venous access	Maintain blood pressure and urine output	Monitor pulmonary function	Consider heparin
Monitor vital signs	Diuretics	Oxygen therapy	Platelet transfusions
ICU transfer	Dopamine	Ventilator support	Plasma for coagulopathy
Pulmonary artery catheter	Dialysis		Protein C

DIC, disseminated intravascular coagulation; ICU, intensive care unit.

results due to clinically insignificant antibodies or other contaminating substances. In the case of AHTR, in which the culprit is most commonly a sampling problem en route to the laboratory, increased sensitivity in testing is unlikely to offer any real progress.

Another common teaching by transfusion professionals is to avoid unnecessary transfusions, in part to reduce the fear that they may cause adverse consequences such as AHTR. Most hospitals have reduced their transfusion trigger for RBCs[22] largely to handle concerns about infectious complications, so transfusion avoidance is not likely to reduce the rate of AHTR significantly.

Because safe blood transfusion continues to depend on well-trained practitioners to obtain samples and administer blood products, it seems unlikely that enhanced training programs will ever totally eliminate this significant problem that is largely caused by human error. Technologic developments that might better handle this problem should be encouraged. The evolving capability to create universal group O blood by enzymatically removing A and B blood group antigens from RBC might be a technologic solution to the serious problem of AHTR.[23]

DELAYED HEMOLYTIC TRANSFUSION REACTIONS

In contrast to AHTR, in which clinical symptoms occur immediately or within 24 hours of transfusion, *delayed* hemolytic transfusion reactions (DHTRs) are generally not recognized until 3 to 10 days after transfusion of blood that appeared to be serologically compatible.[24–26] DHTRs commonly occur in patients who have been immunized to foreign blood group antigens during previous transfusions and/or pregnancies, but the antibody decreases over time and is not detected in subsequent pretransfusion testing. An anamnestic response is stimulated by the transfusion of seemingly compatible blood, causing increased production of antibody that sensitizes the antigen-positive donor RBCs leading to intravascular and/or extravascular hemolysis. Although the clinical symptoms associated with DHTRs are generally milder than those observed in AHTRs, DHTRs with severe hemolysis leading to disseminated intravascular hemolysis and acute renal failure have been reported.[27–30] Because a time delay occurs between transfusion and the appearance of clinical sequelae in these cases, clinicians may not suspect DHTR.[30] Often it is the blood bank or transfusion service that initiates the investigation of DHTR, prompted by the serologic findings observed in post-transfusion testing.[30]

Definition and Incidence

Mollison[24] defined DHTR as accelerated destruction of transfused red cells that begins only when sufficient antibody has been produced as a result of an immune response induced by the transfusion. Since the first case of DHTR attributed to Boorman and colleagues[31] was reported in 1946, numerous cases have been described in the literature.[32–37] Although exceptions are found,[38–42] most DHTRs share these characteristics:

1. DHTRs generally occur in patients who have been alloimmunized to RBC antigens by previous transfusions or pregnancies.
2. Because the titer has decreased below detectable levels, the implicated antibody is not detected in pretransfusion antibody screening or compatibility testing.
3. DHTR is usually suspected 3 to 10 days after transfusion, when clinical symptoms associated with hemolysis are observed and/or serologic findings consistent with DHTR are noted (Table 49–4).
4. The clinical symptoms most frequently associated with DHTR include unexplained decreases in hemoglobin and hematocrit, fever, and jaundice.
5. The hallmark serologic findings in DHTR are the development of a positive direct antiglobulin test (DAT) and/or a positive antibody screening test in post-transfusion testing because of the presence of RBC antibodies that were not detected in pretransfusion testing.
6. Antibodies directed against Rh (CEce) and Kidd (Jk^a, Jk^b) system antigens are the antibodies most commonly implicated in DHTR; however, numerous other specificities have been described.

The frequencies of DHTR reported in early studies vary widely.[29,36] In the first series conducted at the Mayo Clinic from 1964 to 1973, the incidence of DHTR was reported as 1 DHTR per 11,650 RBC units transfused, with 22 (96%) of the 23 cases having clinical manifestations of hemolysis, and 3 deaths attributed to DHTR.[29] In the second series from 1974 to 1977, the incidence of DHTR had increased to 1 DHTR per 4000 RBC units transfused, and only 24 (65%) of 37 had clinical evidence of hemolysis; the remaining 13 (35%) demonstrated serologic findings consistent with a DHTR, but no clinical or laboratory evidence of hemolysis was associated with transfusion.[36] This

Table 49–4 **Time Line of DHTR**

Time (days)	Event	Explanation
0	Pretransfusion tests negative	Antibody titer below detectable levels
1	Red cell transfusion	
3–10	Clinical signs of hemolysis may appear	Accelerated destruction of transfused donor RBC
10–21	Post-transfusion sample: Positive DAT and positive antibody screen due to newly detected antibody	Antibody titer increases; sensitizes donor red cells
>21	DAT may become negative	In vivo removal of antibody-sensitized donor red cells from the circulation
>21 to 300 days	DAT may persist as positive; eluates may demonstrate alloantibody specificity or panagglutination	Alloantibody binding nonspecifically to autologous RBC, or development of warm autoantibodies

DAT, direct antiglobulin test; DHTR, Delayed hemolytic transfusion reaction; RBC, red blood cell.

trend of increased frequency, but decreased clinical significance, appears to be related, in part, to the manner in which DHTRs were defined. If the frequency of DHTR is determined on the basis of clinical reporting alone, then the incidence would be far lower than the true rate, because the signs and symptoms of hemolysis are nonspecific and may be difficult to distinguish from the complicated medical course of multitransfused patients.[26,27] If DHTR is defined by post-transfusion serologic testing, then the frequency is likely to increase, and the clinical findings may diminish, because correlation between serologic results and clinical hemolysis is often poor.[30]

The definition of DHTR was clarified by Ness and colleagues[30] in 1990, when the authors introduced the term delayed *serologic* transfusion reaction (DSTR) to describe cases with serologic evidence of DHTR (i.e., the development of a positive post-transfusion DAT result and a newly identified alloantibody in eluate studies or plasma studies or both), but no clinical evidence of hemolysis. The authors strictly defined DHTR as a subset of DSTR in which clinical evidence of hemolysis was attributable to a transfusion reaction. In their series at the Johns Hopkins Hospital, only 6 (18%) of 34 consecutive patients identified with serologic findings consistent with DHTR had clinical evidence of hemolysis associated with transfusion and could be defined as DHTR by strict definition. Twenty-eight (82%) of the 34 DSTR cases had no clinical evidence of hemolysis, as determined by retrospective chart review. The ratio of DHTR to DSTR can be expressed as 18:82 (Table 49–5). The combined frequency of DSTR and DHTR was calculated as 1:1605 (0.06%) RBC units transfused. The frequency of true DHTR was only 1 case per 9094 units (0.01%) transfused.

By using the same definitions as prescribed by Ness and colleagues,[30] the Mayo Clinic reported a combined frequency of DHTR/DSTR as 1 per 1899 allogeneic RBC units transfused with a DHTR/DSTR ratio of 36:64 when patients were evaluated for clinical hemolysis concurrent with the detection of positive post-transfusion serology.[43] The most recent study from the Mayo Clinic spanning the years 1993 to 1998 indicates a decline in DHTR and a concomitant increase in DSTR, which the authors attributed to the implementation of a more-sensitive antibody screening method and a decrease in the average length of hospital stay for inpatients.[44] Interestingly, their current rates of observed reactions and the DHTR/DSTR ratio are very similar to those reported by Ness and colleagues[30] in 1990 (see Table 49–5).

Diagnosis

The blood bank plays an important role in recognizing and reporting potential cases of DHTR. The clinician may submit a post-transfusion sample with a request for RBC transfusions, not suspecting that the patient's decreased hemoglobin and hematocrit are due to DHTR. Generally, positive antibody screening tests on the post-transfusion sample trigger antibody-identification studies and investigation of DHTR. The laboratory investigation of DHTR is outlined in Table 49–6. The serologic findings in classic cases of DHTR include the development of a post-transfusion positive DAT that may have a mixed-field appearance because of the presence of IgG antibody–sensitized donor RBCs interspersed with DAT-negative autologous RBCs and the presence of a newly identified alloantibody in the red cell eluate or plasma studies or both approximately 3 to 10 days (or usually by 20 days) after the index transfusion (see Table 49–4).[26] If the patient's transfusion history and post-transfusion serologic findings are consistent with DHTR, then the patient should be evaluated for clinical and laboratory evidence of hemolysis associated with RBC transfusions (see Table 49–6). The patient's physician should be notified, and a transfusion reaction report should be generated so that the findings become a part of the patient's medical records.

Serologic Complexities of DHTR

Diagnostic Difficulties

For many years, it was generally accepted that in DHTR, the sensitized donor red cells would be removed from the circulation within approximately 14 days (or no later than 21 days) after the putatively responsible transfusion (see Table 49–4).[26] Therefore, DAT and eluate studies should become negative coinciding with the in vivo destruction of transfused donor RBCs that provoked the immune response. It is now clear from long-term studies of DHTR that it is not uncommon for DAT to persist as positive because of IgG antibody or complement sensitization or both of RBCs for many weeks or months after the transfusion reaction, long after the transfused, antigen-positive donor RBCs would be expected to be removed from the circulation.[30,45] In addition, these long-term studies showed that eluates prepared from samples drawn more than 6 months after DHTR, when all the transfused donor RBCs would have been removed from circulation, may still demonstrate the alloantibody responsible for the reaction. Several theories are proposed to explain these remarkable phenomena.[26,45] Salama and Mueller-Eckhardt[45] suggested that alloantibody binds nonspecifically in vivo to antigen-negative autologous red cells and activates complement via the classic pathway in all DHTRs. Thus DAT may remain positive long after the removal of transfused donor RBCs because of nonspecific sensitization of autologous RBCs with alloantibody or complement or both during DHTR.[45–48] Although the mechanisms remain unclear and a subject of contention, the persistence of a positive DAT and reactive eluates after DHTR does not generally appear to correlate with in vivo hemolysis.[26,30] The practical application of these long-term

Table 49–5 **Incidence of Delayed Hemolytic Transfusion Reaction and Delayed Serologic Transfusion Reaction**

Series	Incidence*	DHTR/DSTR
Ness et al[30] Johns Hopkins Hospital (Jan 1986–Aug 1987)	1:1605	18:82
Vamvakas et al[43] Mayo Clinic (1980–1992)	1:1899	36:64
Pineda et al[44] Mayo Clinic (1993–1998)	1:1300	19:81

*Incidence expressed as DHTR/DSTR per number of red cell units transfused.

Table 49–6 Outline for Laboratory Investigation of Suspected DHTR

1. **Initial Serologic Investigation**
   Post-transfusion sample tests
   Antibody identification studies: Initiated as a result of positive antibody screening tests (and/or positive DAT results) on the post-transfusion sample
   DAT profile: (DAT with polyspecific and monospecific anti-IgG and anti-C3 antiglobulin reagents)
   Eluate studies: Performed if DAT positive due to IgG sensitization of RBC and history of recent RBC transfusions
2. **Supplemental Serologic Tests**
   Retrieve pretransfusion sample (if available): Perform DAT and repeat antibody screening tests
   Retrieve retained segments from transfused RBC donor units: Phenotype for antigen corresponding to identified antibody
3. **Review Serologic Findings and Transfusion History**
   Results evaluated by transfusion medicine attending physician
4. **Generate Suspected Transfusion Reaction Report**
   The transfusion medicine attending physician assesses the patient for clinical signs and symptoms of DHTR and notifies the patient's physician

studies of DHTR is the recognition that serology consistent with DHTR may persist long after the reaction has occurred and the patient has recovered. Consequently, serologic findings alone can be misleading and difficult to interpret. The investigation of DHTR must consider not only the serologic findings, but also the temporal relation of antigen-positive RBC transfusions to the serologic test results, coupled with a clinical evaluation and laboratory assessment of the patient for evidence of hemolysis associated with RBC transfusions.

DHTR and Autoantibody

Many anecdotal cases of allo- and autoimmunization occurring concurrently have appeared in the literature over the past 40 years.[49–59] For example, Lalezari and colleagues[55] described a patient who had DHTR due to allo-anti-D and subsequently developed autoantibodies. The post-transfusion DAT remained positive for 6 months after DHTR, and eluates demonstrated panagglutination consistent with the presence of warm autoantibodies having a broad specificity. Worlledge[54] noted as early as 1978 that alloimmunization can lead to autoimmunization and that even immunized recipients who are given compatible blood may subsequently develop a positive DAT because of autoantibodies. It is not surprising that long-term studies by Ness and associates[30] found that the development of warm autoantibodies after DHTR was relatively common. Approximately one third of patients with DHTR who were followed for more than 25 days after DHTR had persistence of a positive DAT due to warm autoantibodies with broad specificity (i.e., eluate panagglutinin) (see Table 49–4). The frequency of autoantibody development after DHTR may be even higher, because autoantibodies can mimic alloantibody specificities.[58,59] It is possible that DHTR cases with apparent alloantibody recovered in long-term eluate studies may actually represent cases of warm autoantibodies mimicking alloantibody specificities.[30,45] Although the postreaction autoantibodies appeared to be clinically benign in the cases followed by Ness and colleagues,[30] some reports indicate that DHTRs have evolved into the production of pathologic warm autoantibodies leading to severe autoimmune hemolytic anemia.[49–53]

Severe DHTR

Fortunately, the clinical symptoms in most DHTRs generally resolve within 2 to 3 weeks of the index transfusion without medical intervention other than transfusion support with appropriate antigen-negative blood transfusions. However, severe DHTR with life-threatening anemia has been reported and occurs most often in alloimmunized patients with sickle cell disease (SCD).[60,61] Because patients with SCD have a high alloimmunization rate ranging from 17.6% to 36%, they are at greater risk for DHTR.[62–67] Frequencies of DHTR in SCD range from 4% to 22%[63,66,69,70] compared with the frequency of true, clinical DHTR in all transfused patients of only 0.04% (one DHTR per 2537 transfused patients)[71] to 0.1% (one DHTR per 854 transfused patients).[30]

The diagnosis of DHTR in patients with SCD may be difficult. Patients may have symptoms that are misdiagnosed as sickle cell pain crisis, and delays in initiating appropriate treatment could lead to significant morbidity or even death.[72–77] Confusion can be avoided by making certain that an accurate transfusion history is obtained on admission and that a sample is sent to the transfusion service for processing in the event that blood transfusions are required.

The causes of severe DHTR in SCD are unclear and controversial. Explanations for the profound anemia observed in severe DHTR include bystander hemolysis, sickle cell hemolytic transfusion reaction syndrome, and hyperhemolysis.[60,61,78,79]

Bystander hemolysis has been defined as the immune destruction of autologous RBCs that may occur during DHTR. The mechanism(s) of bystander hemolysis is unclear. One theory has proposed that activation of complement could occur when alloantibodies react with transfused antigen-positive donor RBCs, leading to destruction of allogeneic and "innocent bystander" autologous red cells.[80–82] Bystander hemolysis is difficult to document but may be suspected when post-transfusion reaction hemoglobin and hematocrit are less than the pretransfusion values, suggesting that simultaneous destruction of transfused donor RBCs and autologous RBCs may be present. The phenomenon of bystander hemolysis in DHTRs has been reported in patients without SCD.[80–82] However, bystander hemolysis may actually be more prevalent in patients with SCD, because sickle cells have a regulatory defect in the formation of the complement membrane attack complex, causing the cells to be more susceptible to complement-mediated hemolysis.[83] Garratty[71] suggested that complement activation in these cases may be triggered not only by antibody reacting with transfused RBC antigens, but also by antibody reacting with other foreign antigens (e.g., human leukocyte antigen [HLA], plasma proteins). Thus the mechanism of bystander hemolysis during DHTRs in patients with

SCD may be similar to that of paroxysmal nocturnal hemoglobinuria (PNH), in which immune complex formation may result in hemolysis of "innocent" autologous RBCs.[82]

One well-documented case of bystander hemolysis was reported by King and coworkers[60] in a study in which they monitored five patients who had DHTR after preoperative exchange transfusions. By monitoring the hemoglobin A (transfused allogeneic donor RBCs) and hemoglobin S (autologous sickle cells) levels, the authors showed that in one of the cases, a substantial loss of autologous RBCs occurred (i.e., bystander hemolysis), as well as loss of allogeneic RBCs during DHTR.

Petz and colleagues[61] reported five cases of hemolytic transfusion reactions in SCD in which the severe anemia appeared to be due to the destruction of transfused donor RBCs coincident with suppression of erythropoiesis. The authors defined these cases as "the sickle cell hemolytic transfusion reaction syndrome," in which reticulocytopenia coupled with the hemolysis of transfused donor RBCs caused life-threatening anemia. In their series, none of the patients appeared to have accelerated autologous RBC destruction (i.e., bystander hemolysis).

Hyperhemolysis is a term that has been used to describe severe DHTR in SCD in which the ongoing hemolysis of autologous cells seems to be accelerated during the course of a hemolytic reaction.[78,79] Win and associates[78] suggested that the accelerated destruction of autologous cells that may occur in DHTR could be due to hyperactive macrophages that readily sequester both mature RBCs and reticulocytes. Interestingly, Darabi and Dzik[84] recently reported hyperhemolysis after DHTR due to anti-K1 in a patient without SCD.

Treatment of Severe DHTR

Regardless of the mechanisms that may be involved, it is important to recognize that severe DHTR in patients with SCD is not an infrequent finding and may mimic a painful crisis.[72–77] Effective treatment requires prompt diagnosis and conservative transfusion support with appropriate antigen-negative RBCs. Steroid therapy and intravenous immune globulin infusions have been successfully used for the treatment of the most severe cases.[78,79] Some have suggested administration of recombinant erythropoietin, depending on the patient's reticulocyte count.[85]

Prevention of DHTRs

The frequency of DHTRs has diminished with implementation of improved pretransfusion antibody-screening methods.[44] The current challenge is to find a rapid, automated antibody-screening method that is sufficiently sensitive to detect most clinically important antibodies, but not so highly sensitive that clinically benign, unwanted antibodies are detected.[86] Because antibody titers may decline below detectable levels, it is important that clinically significant antibodies be well documented in the transfusion service and medical records, and it may be helpful to provide patients with personal identification cards listing the antibodies and transfusion requirements.[87,88] It must be emphasized that patients diagnosed with DSTRs are at risk for severe DHTR with future transfusions and must receive donor blood negative for the antigen(s) corresponding to the implicated alloantibodies.[26,30]

The high rate of alloimmunization and the high risk of DHTRs in SCD appears to be due, at least in part, to the disparity in antigen frequencies between the African American recipient and white donor population.[63] For example, 73% of African Americans are C negative and may develop anti-C antibodies when transfused with blood from white donors, because 70% of whites are C positive. Therefore, increasing African American donations, particularly if the donations could be linked to patients with SCD requiring transfusion support, might be of benefit.

It is generally accepted that patients with SCD should be extensively phenotyped (e.g., Rh antigens [CEce], K1, MNSs, Fy^a, Fy^b, Jk^a, Jk^b) so that antibodies the patients may potentially produce can be easily discerned.[89–91] Having the extensive or complete phenotype on file is particularly advantageous in resolving complex antibody problems that are frequently presented by multitransfused patients with SCD. DNA typing for RBC antigens is now available and can be used in cases in which phenotyping is precluded by recent RBC transfusions or by scarcity of rare antisera.[92,93]

Prophylactic antigen matching of donor RBCs with the recipient's complete phenotype has been advocated for patients with SCD in an effort to reduce the rate of alloimmunization and severe DHTR.[89,90,94] Various transfusion protocols that differ in the number of antigens that are considered for prophylactic matching have been examined by Castro and colleagues[94]

Ness[91] has proposed that prophylactic antigen matching should be considered only when the patient has developed one or more RBC alloantibodies, thereby indicating that the patient is a "responder" and may be at greater risk for further alloimmunization and DHTRs with subsequent RBC transfusions. This protocol is particularly appealing because it avoids unnecessary prophylactic antigen matching of donor blood for the approximately 70% of patients with SCD who do not become alloimmunized even after multiple transfusions.

Prophylactic antigen matching may prevent some cases of DHTR, but even protocols that call for extensive prophylactic antigen matching cannot prevent severe hemolytic transfusion reactions due to unusual alloantibody specificities or the development of pathologic warm autoantibodies.[60,95–97]

FUTURE DIRECTIONS

The development of blood substitutes for transfusion and/or exchange transfusion in SCD seems to offer the most hope for preventing severe DHTR and for circumventing difficulties in providing compatible blood for patients with complex antibody problems.[98,99]

With the rapidly growing sophistication of DNA technology, we may be able to distinguish "responders" from "nonresponders" by genotyping, so that special transfusion protocols could be applied more appropriately. Automated technology for rapid genotyping of blood donors is already under study and may permit the provision of genotype-matched donor blood to recipients in the near future.[100]

Chapter 50

Febrile, Allergic, and Other Noninfectious Transfusion Reactions

Nancy Heddle • Kathryn E. Webert

The transfusion of blood and blood products can be associated with a number of different noninfectious complications. The frequency of these events is variable, depending on the type of blood product being transfused and the patient population requiring the product. It is useful to categorize these types of reactions as acute (occurring during or within 8 hours of the transfusion) or delayed (presenting a week or two after transfusion), as this will facilitate the differential diagnosis and identification of these adverse events. The challenge for physicians and health care providers when these reactions occur is, first, to recognize that the reaction may be transfusion associated, and second, to use the clinical signs, symptoms, and situation to identify systematically the differential diagnosis, the reaction type, and the cause so that appropriate treatment and prevention strategies can be used. These challenges are complicated by the fact that many of the clinical signs and symptoms are common to several different types of reactions and that comorbidities may complicate the recognition of these events. In this chapter, the immediate and delayed noninfectious complications to transfusion are summarized in terms of their definition, manifestation, prevalence, pathophysiology (when known), diagnosis, treatment, and prevention. An approach is presented to illustrate how this information can be used to work systematically through the complex clinical presentation, generate a differential diagnosis, and identify the cause of the event.

ACUTE NONINFECTIOUS TRANSFUSION REACTIONS

Most of the acute noninfectious reactions occur during a transfusion or within a few hours of the transfusion; however, in some situations, signs and symptoms may not present until 6 to 8 hours after transfusion.[1] As the interval between the transfusion and presentation of symptoms increases, it becomes less likely that the reaction will be recognized as transfusion related; hence it is important for physicians to be aware not only of reactions with early presentation but also of those reactions with delayed onset. The noninfectious reactions in the acute category include febrile nonhemolytic, allergic, anaphylactic, transfusion-related acute lung injury (TRALI), hypotensive, transfusion-associated circulatory overload (TACO), hemolytic reactions (immediate and delayed), and a variety of metabolic complications (Tables 50–1 and 50–2). Hemolytic reactions, TRALI, and bacterial

Table 50–1 **Summary of the Signs and Symptoms Typically Observed with Different Types of Acute Reactions to Blood and Blood Products**

	Types of Symptoms					
	Cutaneous	Inflammatory	Pain	Respiratory	Cardiovascular	GI
Reaction Type	Pruritis Urticaria Erythema Flushing	Fever Chills Shakes Cold Feeling Rigors	Headache Chest Back Abdominal Site of Infusion	Hoarseness Stridor Lump in Throat Wheezing Chest Tightness Substernal Pain Dyspnea Cyanosis	Hypotension Loss of Consciousness Shock Tachycardia Cardiac Arrhythmias Cardiac Arrest	Nausea Vomiting Abdominal Cramps Diarrhea
Hemolytic		X	X	X	X	X
Allergic (mild)	X					
Allergic (anaphylactic)	X			X	X	X
FNHTR		X	x			x
TRALI		X		X	X	
Bacterial sepsis		X	X	X	X	X
Hypotensive	x			x	X	x
Circulatory overload (TACO)			x	X	X (hypertension)	

X, typical symptoms; x, symptoms sometimes observed; GI, gastrointestinal; FHNTR, febrile nonhemolytic transfusion reaction; TRALI, transfusion-related acute lung injury.

Table 50–2 **Summary of the Incidence, Etiology, Treatment, and Prevention of Noninfectious Transfusion Reactions**

Type of Acute Reaction	Incidence (per 100 transfusions)[6]	Incidence (per 100,000 transfusions*)[6] or incidence (per 100,000 patients**)	Etiology	Treatment	Prevention
Acute hemolytic reactions		*Red cells: 1.1–9.0	1. Pre-existing antibody in the patient's plasma binds to an incompatible antigen on the transfused red cells causing destruction. 2. Antibody in donor plasma binds to the patient's red cells causing hemolysis	Stop the transfusion. Notify transfusion service. Send appropriate samples to investigate. Provide supportive care including intravenous fluids. Maintain urine output. Treat DIC and shock as required.	Follow SOPs (clinical areas and laboratory) to ensure appropriate sample, patient and product identification. Ensure all staff are educated to the importance of these procedures.
Delayed hemolytic transfusion reaction (DHTR)		*Red cells: 0.7–24.9	Patient is alloimmunized (sometimes primary but usually secondary) by the transfusion and the antibody binds to the transfused red cells causing destruction.	Supportive care, if required. No specific treatment usually indicated.	Blood for future transfusions should be antigen negative.
Delayed serologic transfusion reaction (DSTR)		*Red cells: 28.9–68.4	Can be caused by active or passive antibody binding to the red cells and causing a positive DAT. No clinical signs of hemolysis.	No treatment required. Observe patient to ensure that delayed hemolysis does not occur.	Future transfusions should be with antigen-negative blood
Febrile nonhemolytic reactions (FNHTRs)	Red cells: 0.07–6.8 Platelets: 0.13–37.5		Red cells: Most reactions are due to a white cell antibody in the patient's plasma that interacts with leukocytes in the red cell product. Platelets: Storage generated proinflammatory cytokines cause of reactions; white cell antigen/antibody interactions cause about 9% of reactions.	Discontinue transfusion. Antipyretics. Supportive care.	Premedication with antipyretics. Leukoreduced blood products (must be prestorage LR for preventing platelet reactions. Other options include fresher products, plasma reduced, or washed cellular products.
Mild Allergic	Red cells: 0.02–1.07 Platelets: 0.06–7.6 All components: 3.0		Soluble antigens in the donor plasma react with IgE bound to mast cells causing histamine release.	Temporarily stop the infusion keeping line open with saline. Administer antihistamines. If urticaria abates, transfusion may be restarted.	Pretransfusion medication with antihistamine.

Anaphylactic		*Red cells: 0.3–4.3 *Apheresis platelets: 7.7 *Platelet pools: 62.5 *All components: 2.1	Patient is IgA deficient and has IgG antibodies to IgA. Other possible mechanisms: antibodies to other serum proteins absent in the patient; transfused allergens; passive transfer of IgE; mast cell activation by anaphylactoxins.	Discontinue transfusion; antihistamine administration. Subcutaneous, intramuscular, or intravenous epinephrine if needed. Supportive care.	Depends on the reaction severity and etiology. Anaphylactoid reactions may be prevented by antihistamine use. Anaphylactic reactions may require avoidance of all plasma containing products if reaction is due to anti-IgA or stringent washed cellular products.
TRALI	Red cells: 1–11 Platelets: 1–46 Not specified: 7–36		Multiple causes: passive transfusion on leukocyte antibody in the donor plasma. Storage generated lipids in the blood product (two-hit model). Other mechanisms not yet understood.	Supportive care only. No specific therapy indicated.	Removal of donors with potent leukocyte antibodies from the donor pool. Transfusion of fresher blood products or washed blood products may have a lower risk of causing these reactions.
Transfusion-associated circulatory overload (TACO)		**All products: 16.8–8000*	Infusion of too much fluid into the circulation in a short time. Patients with cardiovascular disease at greater risk.	Stop the transfusion. Diuretics and supplemental oxygen therapy.	Recognize patients at high risk for TACO. Administer transfusion slowly (split units if necessary). Use of diuretics.
Transfusion-transmitted bacterial infection (TTBI)† Deaths from TTBI		*Platelet pools: 1.1–47.5† *Apheresis: 1.0–7.5 *Red cells: 0.02–1.5 *Platelet pools: 0.2–6.3 *Apheresis: 0.2–1.5 *Red cells: 0–1.0	Bacteria in the blood product release endotoxin or once in the patient's circulation cause infection.	Stop the transfusion. Provide aggressive supportive therapy including broad-spectrum antibiotics.	Inspect all blood products for visual evidence of contamination before infusion; employ measures at the blood center and transfusion service to decrease risk.
Hypotensive reactions	Unknown		Mediated by kinins generated by activation of the contact system. Patients on ACE inhibitors appear to be more susceptible.	Stop the transfusion.	Avoid the use of negatively charged bedside leukoreduction filters.
Post-transfusion purpura	Unknown		Recipient has alloantibody directed against an antigen on the donor's platelets. Patient's own platelets are also destroyed: mechanism not clearly understood.	IVIG infusions are the first-line therapy. Plasmapheresis may also be effective. Patients may respond to antigen-negative platelets if bleeding.	Future transfusions should consist of platelets negative for the antigen to which the antibody is directed (i.e., HPA-1a negative).

*The higher rate was observed in elderly patients (mean age, 67 years) undergoing hip or knee surgery.
† One study from Hong Kong reported the risk of TTBI with platelet pools to be 280/100,000 transfusions; however, all other reports have ranged between 1.1 and 47.5.

contamination are summarized in Chapters 41, 43, and 50, respectively; further clinical details on these complications are not presented. However, these two complications are included in the practical approach to classify acute transfusion reactions described at the end of this chapter.

FEBRILE NONHEMOLYTIC TRANSFUSION REACTIONS

Definition/Manifestations/Prevalence

Febrile nonhemolytic transfusion reactions (FNHTRs) have traditionally been defined as a temperature increase of at least 1° C with or without chills, a cold sensation, or discomfort, occurring during or within a few hours of the transfusion.[1] However, increasing recognition exists that this traditional definition should be modified. Although the name implies that fever is always present, this may not be the case. A recent study has shown that, frequently, the symptoms of chills, cold sensation, and discomfort may occur in the absence of fever.[2] It is not uncommon that the temperature increase is suppressed by the use of antipyretic premedication. Studies performed at our center have shown that FNHTR characterized by chills, cold, and/or discomfort can occur without fever in about 85% of reactions. Severe reactions can be characterized by rigors and, rarely, headache, nausea, and vomiting.[2]

The frequency of FNHTRs varies depending on the type and age of the blood product being transfused, the patient population, and differences in the recording of symptoms by nursing staff and whether premedications are given.[3–5] The reported incidence of FNHTR with red cell products ranges from 0.07 to 6.8 reactions per 100 red cell units transfused.[6] The use of prestorage leukoreduced red cells appears to result in an absolute risk reduction ranging from 0.14% to 0.22%.[7–9] FNHTRs appear to be more common when platelets are transfused; however, the incidence reported in the literature is extremely variable, ranging from 0.19 to 37.5 per 100 platelet transfusions.[6] Historically, FNHTRs have been the most commonly encountered reaction, accounting for approximately 43% to 75% of all transfusion reactions reported at some centers.[10,11] However, centers that use prestorage leukoreduced blood products have seen a dramatic decrease in the frequency of these events, especially those reactions associated with platelet transfusions.[2,7,12]

Pathophysiology

At least two mechanisms seem to result in the clinical manifestations of FNHTR. The first mechanism involves the presence of a white cell alloantibody in the patient's plasma that interacts with white cells in the blood product.[13–15] Both granulocyte[14,16–20] and human leukocyte antigen (HLA) antibodies[18,20] have been implicated in these reactions. This antigen-antibody interaction causes release of endotoxins that act on the hypothalamus, resulting in fever and the other symptoms typical of FNHTR. This mechanism appears to be the primary cause of FNHTR after the transfusion of red cells but accounts for only approximately 9% of platelet reactions.[21] The second mechanism involves the generation of leukocyte-derived cytokines during storage of the product. A variety of cytokines have been detected in stored blood products; however, the proinflammatory cytokines (interleukin [IL]-1, IL-6, IL-8, and tumor necrosis factor [TNF]-α) are likely to be the predominant cause of FNHTR.[21–29] The release and/or production of cytokines during storage occurs mainly at warmer temperatures; hence this mechanism accounts for approximately 90% of the reactions to platelets that are not prestorage leukoreduced, as this product is stored at room temperature but is unlikely to be the cause of red cell reactions, as cytokine production/release is inhibited by the 4° C storage.[30] Therefore, poststorage leukoreduction will be effective at preventing FNHTR to red cells, which are mainly due to white cells in the product, but will have minimal impact on platelet reactions. In contrast, prestorage leukoreduction of both of these products is an effective method for prevention of FNHTR due to both red cells and platelets.[2,7–9] Although this approach has been shown to be effective for preventing most reactions, residual reactions still occur (0.2% for red cells and 1.0% with platelets), suggesting that other minor mechanisms may also play a role.[2] The exact cause of these residual reactions is unknown; however, possible mechanisms that have been suggested include platelet-derived substances such as CD154 (CD40 ligand).[31,32] It has also been postulated that some febrile reactions may represent immune responses to infused substances, such as IL-6, which has been found to be elevated in patients who experience an FNHTR.[33,34]

Diagnosis and Treatment

The diagnosis of FNHTR is one of exclusion. Other causes of fever must be excluded, including other acute transfusion reactions that manifest with fever and clinical comorbidities and/or medications (Fig. 50–1). Sometimes the timing of the reaction may be helpful in the differential diagnosis. FNHTRs tend to be dependent on the dose or concentration of leukocytes and/or cytokines infused and therefore appear toward the end of the transfusion.[1,2,12] It is atypical for this type of reaction to occur during the initial stage of the transfusion. Clinical experience has also suggested that the rate of infusion is another important variable that may contribute to these events.[35]

Treatment of these reactions consists of the administration of an antipyretic such as acetaminophen. Severe shaking chills (rigors) may necessitate meperidine administration. These symptoms resolve with or without treatment and do not typically lead to additional or long-term adverse sequelae. The decision to stop the transfusion requires clinical judgment based on the severity of the symptoms, the type of product being transfused, the timing of the symptoms in relation to the amount of product infused, and the history and clinical state of the patient.[5]

Prevention

The approach for preventing FNHTR differs slightly depending on whether the product is red cells or platelets. For red cell reactions, the first line of prevention would include either poststorage or prestorage leukoreduction. If reactions still occur to leukoreduced products, other approaches that may be effective include the transfusion of fresher blood products and or washed blood products. To prevent FNHTR to platelet transfusions, prestorage leukoreduction has been shown to be the most effective method. For patients who still react to the prestorage leukoreduced product, other options include removing the residual plasma from the platelet product, washing the product, or selecting fresher products

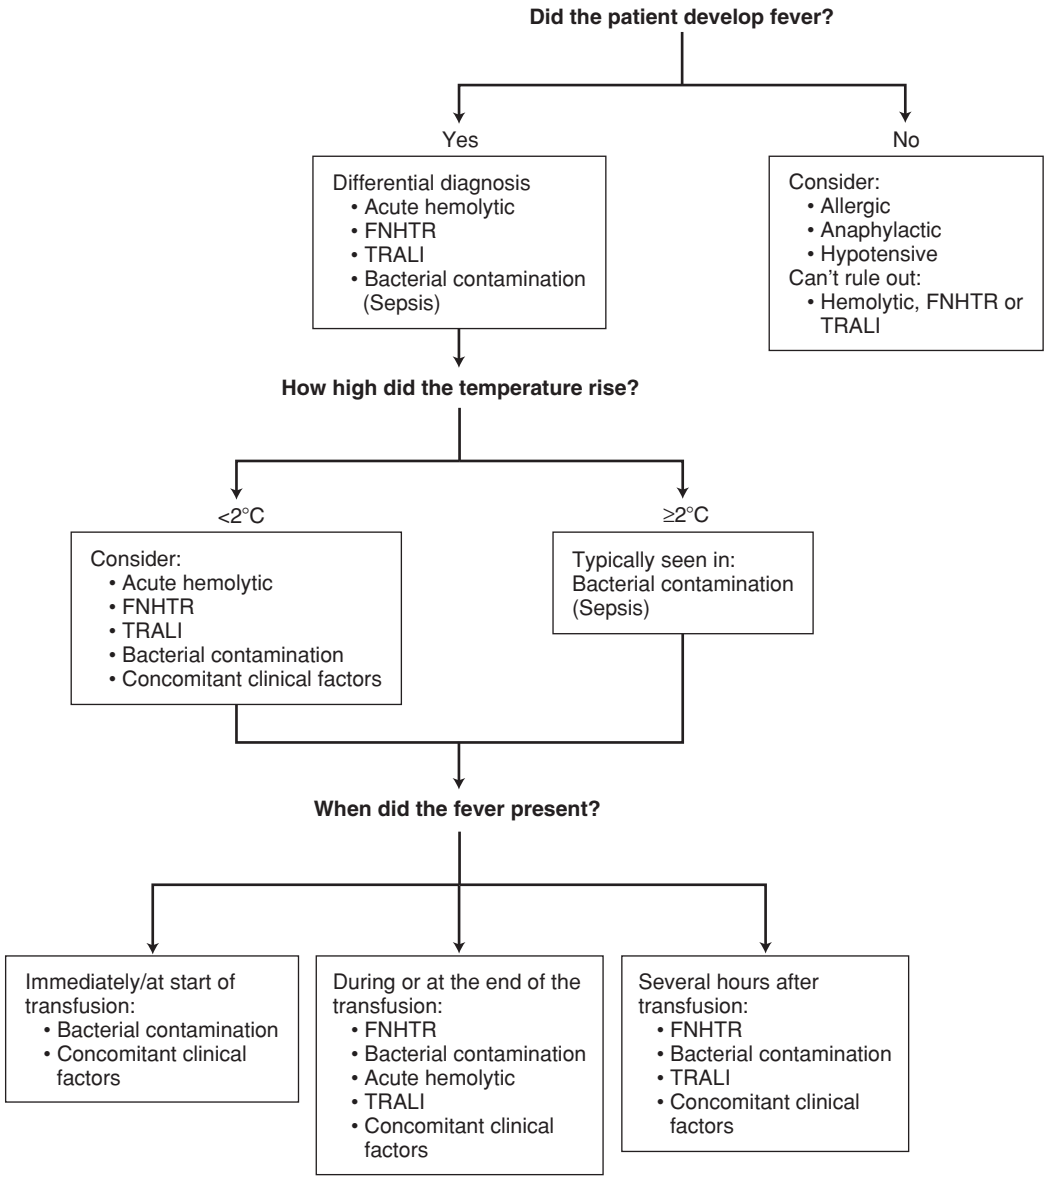

Figure 50–1 Algorithm to assist with the differential diagnosis of acute transfusion reactions associated with fever.

for transfusion.[5] Pretransfusion antipyretic administration may be effective in some patients for preventing recurrent FNHTR. One concern about this strategy is that fever associated with other types of reactions (hemolytic transfusion reactions and reactions to bacterially contaminated products) may be masked. In the past, microaggregate filtration was postulated as a method to reduce the granulocyte concentration, and therefore FNHTR, in red blood cell units.[36,37] However, this did not become common practice and is not generally recommended.

ALLERGIC REACTIONS

Allergic transfusion reactions may be grouped into three categories by severity; however, the categories can have overlapping presentations: (1) uncomplicated allergic reactions, (2) anaphylactoid reactions, and (3) anaphylactic reactions. At the mild end of the spectrum, uncomplicated allergic reactions consist of only cutaneous manifestations. At the severe end of the spectrum are anaphylactic reactions characterized by severe hypotension with a high likelihood of morbidity or mortality due to shock. The term *anaphylactoid* has been used to characterize reactions that are moderate in severity involving cutaneous symptoms as well as some degree of hypotension, stridor, wheezing, dyspnea, chest pain, or tachycardia. As the etiology of the mild allergic reactions is different from that of anaphylactoid and anaphylactic reactions, they are discussed as separate entities.

MILD ALLERGIC REACTIONS

Definition/Manifestations/Prevalence

Mild allergic reactions are characterized by a localized or confluent red raised itching rash (urticaria) in the absence of fever. For a reaction to be classified as uncomplicated urticaria, no additional symptoms must be present, such as asthma-like attacks, coughing, difficulty in breathing, or other symptoms associated with anaphylactoid or anaphylactic reactions.[38,39] Very few well-designed prospective studies provide

information on the incidence of mild allergic reactions. One would anticipate that the incidence would vary depending on the type of blood product, the amount of plasma in the product, and patient population being transfused (see Pathophysiology later). Several studies have reported that mild allergic reactions occur with approximately 3% of all blood products transfused.[40–42] The reported frequency of reactions to platelet transfusions has varied from 0.02% to 7.6%.[2,43–47]

Pathophysiology

These reactions presumably occur as a result of cutaneous hypersensitivity in which the recipient has been previously sensitized to soluble allergens found in the donor unit.[38] The soluble antigen in the donor plasma is bound to immunoglobulin E (IgE) on mast cells, which causes the release of histamine and the cutaneous symptoms typically observed. It is important to note that most allergic reactions appear as a spectrum and that reactions that begin as urticaria may develop into anaphylactoid or anaphylactic reactions, although this is rare.

A recent report suggests that allergic reactions can also occur as delayed events. In this case report, the patient developed urticaria and shortness of breath several days after a plasma transfusion while eating peanut butter. The patient had no known peanut allergies, and serologic investigations demonstrated a potent antibody specific for peanuts in the donor's plasma. Although this case is unusual, it illustrates the importance of considering the transfusion history for patients who experience these types of events.[48]

Diagnosis

Diagnosis of skin-restricted allergy is straightforward and requires recognition of a rash with associated itching but without additional symptoms. As soluble plasma antigens are the cause of these reactions, the reactions tend to be dose dependent, occurring later in the transfusion. The rash resolves when the transfusion is stopped and/or an antihistamine is given.

Treatment

Treatment for uncomplicated urticaria requires temporary discontinuation of the blood-product infusion and administration of an antihistamine. If the symptoms resolve, the transfusion may be resumed, and a formal transfusion reaction assessment is not required. If the symptoms do not resolve or if they progress during treatment or on continuance of the transfusion, the transfusion should be stopped and a new unit obtained.[38]

Prevention

Premedication with an antihistamine will prevent urticarial reactions in most patients who have a history of allergic reactions. If premedication is not effective or if repeated reactions of increasing severity occur, washed cellular products may be beneficial. As donor leukocytes are not involved in the etiology of these reactions, leukoreduction has no role in the prevention of these events. This has been demonstrated in a large observational study of more than 47,000 red cell transfusions, in which the frequency of mild allergic reactions was 0.04% before universal leukoreduction, and 0.06% after implementation of universal leukoreduction.[49]

ANAPHYLAXIS/ANAPHYLACTOID REACTIONS

Definition/Manifestations/Prevalence

Anaphylactic transfusion reactions are severe systemic reactions characterized by hypotension, bronchospasm or dyspnea, nausea, vomiting, diarrhea, and urticaria.[38,50–55] The most serious symptoms include lower airway obstruction, laryngeal edema, and hypotension. Typically, these reactions appear after a small volume (<10 mL) of product has been infused.[1,38] Most reactions occur in patients who are IgA deficient and who have IgG alloantibodies to IgA detectable in their plasma.[52] Although IgA deficiency is not uncommon (1 in 700 individuals), anaphylactic reactions are relatively rare, occurring in of 1 in 20,000 to 1 in 47,000 (0.002% to 0.005%) products transfused,[41] a rate considerably less than the sector of the population thought to be at risk (0.08%).[56] Canadian data suggest that these reactions occur even less frequently, with an incidence of incidence of 0.00013% per unit transfused.[6] Between 1976 and 1985, three deaths were attributed to transfusion-associated anaphylaxis in the United States.[57]

Anaphylactoid reactions are generally less severe than anaphylaxis. Severe and even fatal reactions, however, have been reported in patients with detectable levels of IgA and concurrent specific anti-IgA.[41,50,57–59]

Pathophysiology

Anaphylactic reactions are most commonly due to preformed, class-specific, recipient anti-IgA to infused donor IgA proteins in patients with IgA deficiency.[41] However, other case reports have linked anaphylactic reaction to HLA-associated antibodies in platelet transfusion,[60] anti-C4 in a C4-deficient patient,[61] and antihaptoglobin in an ahaptoglobinemic patient.[62] One study involving 32,376 random blood donors found an IgA deficiency incidence of 0.26% (1 in 372).[56] IgA deficiency with associated anti-IgA in the same study was found to occur at a rate of 0.08% (1 in 1200).[56] From this, one may infer that the incidence of anti-IgA in IgA-deficient donors is approximately 31% (0.26/0.08).

Anaphylactoid reactions are typically associated with subclass, allotypic, or specific anti-IgA in patients who have demonstrable and often normal levels of IgA.[41,50,56,58,59] It is difficult to identify patients who may have a specific anti-IgA because that would involve a seemingly infinite number of specific IgA proteins. These types of reactions may also be due to other transfused products found in donor units, such as peanut allergen transfused to patients who may have peanut allergy.

Diagnosis

Anaphylaxis/anaphylactoid reactions should be recognized immediately when a patient has the symptoms just described. When anaphylaxis related to blood transfusion is suspected, administration of any additional plasma-containing blood product should be avoided, if possible, until an appropriate diagnostic evaluation can be performed. Differential diagnosis of transfusion-related anaphylaxis includes hypotensive reactions occurring in patients taking angiotensin-converting enzyme (ACE) inhibitors, TRALI (Chapter 43), and other events unrelated to transfusion, including myocardial

infarction or pulmonary embolus.[38] When anaphylaxis occurs in association with blood transfusion, IgA deficiency with concomitant anti-IgA must be investigated. For a firm diagnosis, this requires demonstration of recipient anti-IgA.[41,50,52–54,59,63,64]

The initial investigation may include nephelometry for the detection of IgA. Demonstration of IgA by this method effectively negates a diagnosis of anaphylaxis related to anti-IgA. If IgA is not detected, additional studies should be performed because some patients have IgA levels that are below the limit of detection by nephelometry. To detect anti-IgA in these cases, passive hemagglutination assays (PHAs) utilizing IgA-coated red blood cells are performed. Most often, the IgA used to coat these red blood cells is from patients with multiple myeloma whose monoclonal protein is IgA.[41,50,52–54,56,58,59,63–65]

Treatment

In addition to immediate discontinuation of product infusion, treatment of anaphylaxis includes prompt administration of epinephrine, which will quickly reverse the action of histamine. Other supportive care may include vasopressors and airway support. Intravenous steroids and an H_1-receptor antagonist can be given to reduce the risk of protracted anaphylaxis.[38,39]

Prevention

Prevention of anaphylactic reactions in patients who are determined to be IgA deficient with anti-IgA antibodies requires avoidance of transfusion with plasma-containing IgA. Cellular products can be washed to remove the residual plasma containing IgA, or products can be collected from donors who are known to be IgA deficient.[56] When red cells are required, autologous donation and frozen blood may also be feasible options. Most often, IgA-deficient donors are identified by screening immunodiffusion methods[66] followed by a confirmatory passive hemagglutination inhibition assay (PHIA).[56,59,65,67] This assay differs from PHA by the addition of a known amount of reagent anti-IgA and the observation of inhibition of agglutination, which is due to the presence of donor IgA; that is, no agglutination inhibition would be observed in donors who lacked IgA.[51,56,65,68] It is important to use a sensitive method such as PHIA to confirm IgA deficiency in donors. Case reports show that some patients found to be at risk for IgA-deficient anaphylactic reaction were transfused with presumptive IgA-deficient plasma containing products that led to anaphylactic reactions. Retesting of these products by more sensitive methods showed that they contained low levels of IgA.[56]

HYPOTENSIVE REACTIONS

Definition/Manifestation/Prevalence

Hypotension is a relatively rare complication of blood transfusion that is typically seen in TRALI, sepsis due to bacterial contamination, and anaphylactic transfusion reactions. In addition to these transfusion-related complications, another type of reaction characterized by acute hypotension within the first few minutes of a transfusion has been described. These hypotensive reactions are first seen with a decrease in systolic or diastolic blood pressure of at least 30 mm Hg occurring within 10 minutes of starting the transfusion and are distinguishable from other adverse events with hypotension as they resolve rapidly once the transfusion is stopped. Some patients may also have facial flushing, abdominal pain and nausea, loss of consciousness, respiratory distress, and shock.[69] The initial reports of these reactions all occurred in patients taking ACE inhibitors who were transfused blood products through a bedside leukoreduction filter[69–71]; however, the reactions may not always be related to the use of these filters.[72] The overall frequency of these events is not currently known, as reports in the literature have been individual case reports or case series.

Pathophysiology

Hypotensive transfusion reactions are thought to be mediated by bradykinin and des-Arg-bradykinin, which are two vasoactive kinins that are generated by the activation of the contact system. Activated factor XII converts prekallikrein to kallikrein, which cleaves high-molecular-weight kininogen and releases bradykinin. This vasodilatory nonapeptide causes hypotension and edema by activating B2-kinin receptors on the vascular endothelium.[73,74] Bradykinin is rapidly inactivated by ACE; however, if a patient is taking an ACE inhibitor, this inactivation process will be impaired. The original reports of hypotensive reactions occurred with negatively charged bedside leukoreduction filters, which have been demonstrated to result in kinin activation and accumulation. If the patient was taking an ACE inhibitor, kinin inactivation was impaired, and acute hypotension occurred.[75] Other reports documented that these reactions could also occur when positively charged bedside filters were used.[76] We have recently postulated that other factors may contribute to these hypotensive reactions after investigating two patients undergoing radical prostatectomy who were transfused blood by using standard blood filters and a warming device. Possible contributing factors may include activation of the contact system by using the blood warmer; release of prostate specific human glandular kallikrein (hK2) and hK3 (prostate specific antigen) during surgery, which can cause bradykinin generation; and/or an inherent defect in the patient's ability to degrade kinins.[72] Several pathways and factors may contribute to the hypotensive reactions, and further studies will be required to improve our understanding of these adverse events.

Treatment

Hypotensive reactions should be treated by immediately stopping the infusion of the blood product transfusion and by providing the patient with supportive care. Typically, the symptoms resolve quickly once these measures have been taken, as indicated by the two case reports by Arnold and colleagues.[72]

Prevention

Most hypotensive reactions can be prevented by avoiding the use of bedside leukoreduction filters. In 1999, the U.S. Food and Drug Administration (FDA) warned consumers about the risk of hypotensive reactions with bedside leukoreduction filters and recommended the use of prestorage leukoreduction as a safe alternative.[71] Some physicians have also

suggested that ACE inhibitor therapy should be temporarily discontinued just before surgery; however, no clinical data suggest that this is a beneficial and risk-free alternative for preventing hypotensive reactions.

CIRCULATORY OVERLOAD

Definition/Manifestation/Prevalence

TACO appears as acute respiratory distress that begins during or shortly after the administration of a blood product. Symptoms and signs of TACO include dyspnea that worsens as pulmonary edema progresses, orthopnea, chest tightness, cough, tachycardia, hypertension, and widened pulse pressure. TACO generally occurs near the end of administration of the transfusion or within 6 hours of completion. The frequency of circulatory overload varies depending on the patient population being transfused and the blood product being given; however, it has been estimated to occur in about 1% of transfusions and is often unrecognized.[77] Patients at higher risk for TACO include elderly patients, patients of small stature, patients with compromised cardiac function, and small children.

Pathophysiology

It is difficult to overload the circulatory system if a patient has normal cardiac function; however, patients with congestive heart failure or other heart and pulmonary diseases are susceptible to this complication when transfusions are given. Infants are also at increased risk of circulatory overload. The intravascular volume may be overtaxed by either an inappropriate rate of transfusion or an inappropriate volume of transfusion in addition to other infused substances. When cardiac output cannot be maintained, pulmonary edema can occur. The problem can also be magnified in a patient with renal failure.

Diagnosis

The physical examination will reveal the patient to have an elevated jugular venous pulse. Auscultation of the chest will suggest pulmonary congestion with rales and crackles. The cardiovascular examination may reveal the presence of an S3 gallop. Findings suggestive of TACO on radiographic examination of the chest include pulmonary vascular redistribution, alveolar and interstitial edema, Kerley B-lines, cardiomegaly, and pleural effusions.

The measurement of an elevated brain natriuretic peptide (BNP) has recently been proposed as a useful adjunct marker in confirming volume overload as a cause of dyspnea.[78] BNP is a polypeptide secreted from the cardiac ventricles. It is increased in heart failure and fluid overload by ventricular cells in response to increased filling pressures.[79] BNP causes natriuresis and diuresis, vasodilation, and inhibits the renin-angiotensin aldosterone system.[80,81] Zhou and colleagues.[78] demonstrated the use of BNP in patients with suspected TACO to have a sensitivity of 81% and a specificity of 87%. Furthermore, plasma BNP measurement was approved by the FDA as an aid in the diagnosis of heart failure, and it is recommended that measurement of BNP levels should be part of the diagnostic approach to patients with suspected heart failure.

Treatment

Treatment includes the cessation or reduction of the rate of blood-product infusion, the placement of the patient in a sitting position, diuretics, and other supportive therapy such as supplemental oxygen.

Prevention/Recurrence

In general, blood products may routinely be transfused at a rate of 2.0 to 2.5 mL/kg/hr. However, in patients with a previous history of TACO or who are thought to be at an increased risk of TACO (i.e., the elderly, those with poor cardiac function, small infants), this rate should be decreased to approximately 1 mL/kg/hr. When a red cell or plasma product cannot be infused within the 4-hour period specified in safety standards, the product may be split into two parts, with one part being stored at a cold temperature while the other part is slowly infused. Patients considered to be at risk for TACO should be monitored closely during and after the transfusion for signs and symptoms of TACO. Pretransfusion and intratransfusion therapy with diuretics may also be beneficial in patients with any degree of cardiac or renal failure. These medications should never be added directly to the blood product or infused through the same line as the blood product. If a rapid transfusion is required, procedures such as isovolemic exchange transfusion have been described in the literature and may decrease the risk of TACO.[82]

OTHER ACUTE REACTIONS

Metabolic Complications

A number of metabolic complications can occur when blood products are infused. These complications are most commonly observed in neonatal patients or in circumstances in which rapid, large-volume infusions occur. Such metabolic complications include effects of citrate toxicity (hypocalcemia), hyperkalemia, and hypothermia.

Citrate Toxicity

Sodium citrate is the anticoagulant used during blood collection. The final citrate concentration in blood components is highest in plasma products. Normally the liver rapidly metabolizes transfused citrate; however, during massive transfusion, the capacity of the liver for citrate clearance may be exceeded.[83] The citrate forms a complex with calcium, resulting in decreased ionized calcium and a hypocalcemic state. Although transient hypocalcemia is usually well tolerated, nerve cell membranes can be affected, causing perioral or acral paresthesia. Clinical manifestations may include lightheadness, shivers, twitching, and tremors. Severe hypocalcemia can cause continuous muscle contractions and, if not corrected, can progress to tetany with spasms in multiple muscle groups.[84] It is important to recognize early symptoms of hypocalcemia so treatment can be initiated. Oral administration of calcium in antacid tablets and /or milk is commonly used for mild citrate toxicity. If symptoms progress, the infusion may have to be stopped or the flow rate decreased, or parenteral Ca^{2+} supplementation given.[84]

Hyperkalemia

When red cell products are stored, potassium leaks from the cells, increasing the plasma potassium concentration. During

massive transfusion, transient hyperkalemia can occur; however, the cause is probably multifactorial, being related to the patient's acid-base balance, the ionized calcium concentration, the rate of the infusion, and the potassium level in the product.[85–89] In most cases, hyperkalemia can be reversed by correcting the underlying acid-base imbalance and slowing the rate of infusion.

Hypothermia

As red cell and plasma products are stored at cold temperatures, their rapid infusion may contribute to hypothermia, especially in patients with major trauma who may already be susceptible to hypothermia, depending on the nature and extent of the injuries.[90] Hypothermia results in a number of metabolic impairments including a decrease in the rate of citrate and lactate metabolism, increased oxygen affinity of hemoglobin, and increased red cell potassium release.[91–95] In addition, the decreased core body temperature may affect cardiac function with associated morbidity and mortality. Hypothermia can be minimized by warming the blood products before transfusion by using an approved blood-warming device.[96–98]

Red-Eye Syndrome

Other transfusion reactions that have been attributed to leukoreduction filters include ocular reactions, the so-called red-eye syndrome.[99] In all reports of red-eye syndrome, the patient exhibited bilateral conjunctival injection or hemorrhage, which occurred within 1 day of transfusion and had an average duration of approximately 5 days. Other features of the reaction were eye pain, headache, periorbital edema, arthralgias, nausea, dyspnea, and rash.[99] These reactions were predominantly linked to a specific leukoreduction filter, which has since been taken off the market.

DELAYED NONINFECTIOUS TRANSFUSION REACTIONS

Post-Transfusion Purpura

Definition/Manifestations/Prevalence

Post-transfusion purpura (PTP) was initially described approximately 50 years ago.[100–102] It is a rare but serious complication of transfusion. PTP manifests as sudden and severe thrombocytopenia (platelet count $<10 \times 10^9$/L) and purpura occurring within 5 to 10 days (range, 1–24 days) of red cells, plasma, or platelet transfusions.[103] Fevers and chills may occur during the implicated transfusion. The risk of PTP is unknown, but approximately 300 cases are reported in the literature.

Pathophysiology

PTP is generally thought to be caused by recipient alloantibodies directed against donor platelet antigens that the recipient lacks. The alloantibodies are IgG immunoglobulins.[104,105] The most common platelet alloantibody identified in patients with PTP occurs in patients who are homozygous for human platelet-specific alloantigen 1b (HPA-1b) and is directed against HPA-1a, although antibodies of other specificities have been identified.[106–114]

The platelet destruction that occurs includes the transfused platelets as well as the autologous platelets, leading to a profound thrombocytopenia. The mechanism causing the destruction of the autologous platelets is poorly understood. A number of theories have been proposed to explain the clearance of the antigen-negative platelets in the presence of anti–HPA-1a antibodies. The mechanisms proposed include (1) the nonspecific absorption of alloantigen-alloantibody immune complexes to the recipient's own platelets, with subsequent clearance mediated by complement or by the reticuloendothelial system (also known as the innocent-bystander effect)[115]; (2) the binding to autologous platelets of soluble or microparticle-associated alloantigen derived from the destruction of transfused blood product, thus making the recipient platelets a target for the alloantibodies; or (3) the presence of pseudo-specific alloantibodies that are produced in the early phase of the anamnestic response and can bind to determinants on autologous platelets, leading to their destruction.[116,117]

Female patients are approximately 5 times more likely to develop PTP after transfusion than are male patients, because of sensitization during previous pregnancies.[104] Because prior transfusion can also be the initial immunizing event, previously transfused male patients may also develop PTP. Approximately 3% of the white population are homozygous for the HPA-1b antigen and are therefore potentially at risk for PTP, if they are alloimmunized against HPA-1a.[118] However, fewer than 30% of these patients are able to form anti–HPA-1a.The development of such alloantibodies is highly associated with the presence of maternal HLA-DRw52a (HLA-DRB3*0101).[119]

Treatment

The usual treatment for this reaction is intravenous immunoglobulin (IVIG) at a dose of 1 g/kg for 2 days. The mechanism of action of IVIG is not well understood but may involve reticuloendothelial blockade or nonspecific antibody adherence to the target antigen that blocks access by specific antibody. Case reports have suggested that treatment with IVIG may shorten the duration of thrombocytopenia.[108,120–125] If a poor response to IVIG occurs, plasmapheresis may be used to reduce the antibody and possibly soluble antigen titers.[126,127] Corticosteroids, to depress immune system responsiveness, have also been used in the treatment of this disease, but they are no longer generally used because IVIG with or without plasmapheresis is effective therapy. In patients who are bleeding, the transfusion of antigen-negative platelets may provide a good increment of the platelet count and clinical hemostasis.[128,129] In general, routine allogeneic platelet transfusion is not recommended because it may exacerbate the reaction process and does not typically increase the platelet count.

PTP is a serious disorder, with fatal bleeding, usually intracranial or gastrointestinal hemorrhage, occurring in approximately 10% to 20% of patients. If PTP does not lead to death resulting from hemorrhage, it is a self-limited disease, with recovery typically occurring within 4 to 5 days of therapy. Recovery may be hastened by the use of antigen-negative platelets if the specificity of the antibody has been determined and antigen-negative platelets are available.[130,131]

Prevention/Recurrence

Little has been published about the recurrence or prevention of PTP. In general, it is recommended to avoid antigen-positive red blood cell and platelet transfusions in patients in whom PTP has previously occurred. The use of washed

or filtered random red cells has been demonstrated to be effective by some authors[131,132]; however, this practice is not supported by all experts. An additional important consideration is that female patients with a history of PTP are potentially at risk for the delivery of an infant with neonatal alloimmune thrombocytopenia and should be counseled appropriately. Family members should also be counseled.

Iron Overload

Definition/Manifestations/Prevalence

Iron overload is an uncommon complication of transfusion that occurs after long periods in patients who receive red cell transfusions for chronic disease, such as sickle cell anemia and thalassemia.

Pathophysiology

Each unit of red cells contains approximately 200 to 250 mg of iron. The excess iron is initially stored in the patient's macrophages. As iron stores increase, the iron is stored in the liver parenchymal cells, myocardium, and endocrine organs. Chronic iron overload leads to liver dysfunction, heart failure, skin pigmentation, and endocrine disorders such as diabetes mellitus. The toxic manifestations of excess iron stores depend on such factors as (1) the amount of excess iron, (2) the rate of iron accumulation, (3) the ascorbate level, (4) alcohol use, and (5) viral hepatitis infection.[133,134]

Diagnosis

The iron content of different organs may be estimated or measured directly. The serum ferritin, although commonly performed, is a poor measure of total body iron, as it is affected by other variables, such as inflammation. Hepatic storage iron has been demonstrated to correlate with total body iron stores.[135] Liver iron can be measured after liver biopsy or by supraconducting quantum interface device (SQUID) or by magnetic resonance imaging (MRI). Patients with liver iron levels greater than 15 mg of iron per gram of liver are at increased risk for hepatic fibrosis and other complications.[136] Cardiac iron may be indirectly measured by using MRI. Other measures of iron status include the measurement of non–transferrin-bound iron and urine iron excretion. Patients with iron overload should also have the function of potentially affected organs assessed: the heart, liver, and endocrine glands.

Treatment

Transfusion-related iron overload is fatal in patients who are dependent on red cell transfusion, unless these patients are treated with agents that chelate the iron and promote its excretion. Therefore, the goal of iron chelation therapy is to decrease the iron deposition in tissues to levels that will not cause iron-mediated toxicity. Treatment with these agents is usually begun after 10 to 20 transfusions have been given.[137] Desferoxamine (DFO) is the most widely available chelating agent administered subcutaneously or intravenously. Regular chelation therapy with DFO has been associated with decreased hepatic fibrosis, decreased risk of cardiac disease, and decreased risk of endocrine dysfunction.[136,138–140] Because of the inconvenience, expense, and difficulty of treating patients with subcutaneous or intravenous infusion, oral chelating agents are being developed and tested. These agents include deferiprone and deferasirox (ICL 670).

Other Delayed Noninfectious Complications

Transfusion-associated graft-versus-host disease, transfusion-induced refractoriness to platelet transfusion, and other transfusion-related immunomodulations also occur and are discussed in detail in Chapters 44 and 45.

INVESTIGATION OF ACUTE REACTIONS

Most publications dealing with the management of acute transfusion reactions recommend that the transfusion of the blood product should always be stopped when signs and symptoms of a reaction are present while an assessment and transfusion-reaction investigation is performed. This approach is based on many years of experience and observation indicating a direct correlation between the severity of some reactions and the volume of the blood product transfused. Indeed this correlation is true for acute hemolytic transfusion reactions. However, some types of patients may frequently be spiking a temperature because they have sepsis, or may be known to react to almost every transfusion that is given, and stopping and investigating a transfusion every time mild symptoms are observed may not be practical or clinically justified. To provide a single algorithm on when to stop and when to continue a transfusion is not a practical solution because of the many factors that must be incorporated into the decision-making process. This decision requires clinical judgment, and the best way to ensure effective clinical decision making is for all health care professionals to be familiar with the types of reactions that occur and how these reactions appear, and to use a logical approach that balances risk, benefit, and resource utilization. In this section, some of the factors that can assist in the clinical management of transfusion reactions are described.

1. Cutaneous symptoms only: General agreement exists that when mild cutaneous signs and symptoms occur during transfusion with no other clinical manifestations, a transfusion-reaction investigation is not required. Depending on the discomfort experienced by the patient, the transfusion may have to be temporarily stopped and an antihistamine administered. Slowing the rate of infusion may also be of clinical benefit.
2. Did the patient develop fever? Fever is a commonly encountered symptom that can be present with several different types of acute reactions (hemolytic, TRALI, bacterial sepsis) (see Fig. 50–1). The absence of fever when cutaneous symptoms are present is characteristic (and diagnostic) of allergic reactions. However, it is important to remember that more than one type of reaction can occur simultaneously; hence fever and cutaneous symptoms sometimes both occur and should alert one to consider multiple events.
3. How high did the temperature rise? Most transfusion-associated fevers result in a modest increase in temperature (<2° C). A temperature increase above 2° C has been frequently reported in cases where blood products contaminated with bacteria have been transfused; hence bacterial contamination of the blood product should always be considered (and ruled out) when a dramatic increase in temperature occurs.
4. What is the temporal association between the fever and the amount of blood transfused? Noting whether

the fever occurs early or late in the transfusion can also be helpful to identify the type of reaction.

5. Is hypotension present, and when did it present? Hypotension does not occur with mild allergic reactions or with FNHTR. When hypotension is present, the differential diagnosis should include acute hemolytic reactions, anaphylaxis, bacterial contamination, TRALI, hypotensive reactions, or concomitant clinical factors associated with the patient's illness. Hypotension will be seen very early in the transfusion (after 5 to 10 mL of product) when it is related to anaphylaxis or hypotensive reactions, whereas the symptoms associated with acute hemolysis usually require 50 to 100 mL of blood to be infused. Hypotension associated with bacterial contamination and TRALI may occur during the transfusion or up to several hours after transfusion.
6. Did the patient complain of pain? The spectrum of transfusion-related pain can include headache, abdominal pain, flank or back pain, or pain at the site of the infusion. Headaches typically occur in FNHTR, whereas abdominal and back pain are more typically noted with acute hemolytic reactions and the infusion of bacterially contaminated product.

The questions summarized in this section can be used as a guide to assist with establishing a differential diagnosis and to identify systematically the most probable cause of the adverse event. Although these questions will be helpful, many other factors must also be considered, including the patient's clinical condition and diagnosis, a history of previous reactions, the type and age of the blood product being transfused, and medications.

When a transfusion-related adverse event is suspected and clinical findings warrant further investigation, the following approach should be used:

Stop the transfusion, keeping the administration line open with saline.

Provide supportive therapy to the patient if required.

Perform a bedside clerical check to ensure that the right product is being transfused to the right patient.

Document all signs and symptoms on a transfusion-reaction form and notify the Transfusion Service that a reaction has occurred.

If the decision is made to proceed with a serologic investigation to rule out an acute hemolytic reaction, a blood sample should be collected and sent to the laboratory for investigation. In most situations, the laboratory can perform three basic tests/procedures that will indicate whether a reaction has occurred: a clerical check of laboratory records, visual examination of the patient's plasma for free hemoglobin, and a direct antiglobulin test. If all three of these procedures are negative or show no discrepancy, then it is unlikely that the reaction is due to acute hemolysis; however, if the clinical manifestations support a diagnosis of hemolysis, then further serologic investigations may be warranted. All reactions must be documented in the patient's chart. In all cases in which the transfusion is thought to cause or contribute to death, appropriate notifications should be made. In the United States, the FDA must be notified by phone within 24 hours after discovery, and this must followed up with a written report within 7 days (21 CFR 606.170). Specific requirements vary by country.

If the decision is made to continue the transfusion, the patient should be closely monitored for signs and symptoms suggestive of a more severe transfusion reaction. If these occur, the transfusion should be stopped immediately.

CONCLUSION

This chapter has provided an overview of acute and delayed noninfectious complications of blood transfusion. When reactions occur, all clinical signs and symptoms must be documented, and, based on these observations, a differential diagnosis should be established. When working through the differential diagnosis, it is helpful to consider the presence or absence of fever and when it occurred, and whether hypotension, pain, or cutaneous signs and symptoms were present. Laboratory tests to rule out acute hemolytic reactions or to identify contaminated blood products are readily available in most hospitals; however, the other types of acute noninfectious transfusion reactions are typically based on a clinical diagnosis. For some types of reactions, confirmatory laboratory tests are possible; however, this usually involves the referral of samples to a specialized reference laboratory and a delay of days to weeks before results are available. For this reason, it is important that health care professionals be familiar with how acute and delayed noninfectious transfusion reactions occur to ensure an accurate clinical diagnosis that will facilitate effective treatment and optimal methods for preventing future reactions.

Chapter 51

Transfusion-Related Acute Lung Injury

Kathryn E. Webert • Steven H. Kleinman • Morris A. Blajchman

Transfusion-related acute lung injury (TRALI) is a complication of allogeneic blood transfusion, typically manifested by shortness of breath due to noncardiogenic pulmonary edema, fever, and hypotension. The first description of noncardiogenic pulmonary edema after an allogeneic blood transfusion was reported in 1951, and TRALI was recognized as a distinct clinical entity in the 1980s.[1,2] TRALI has been recognized increasingly as an important cause of transfusion-associated mortality. The United States Food and Drug Administration (FDA) recently observed TRALI to be the leading cause of transfusion-related deaths reported to the agency in 2003.[3] The Serious Hazards of Transfusion (SHOT) Annual Report for 2003 reported that, in Great Britain, TRALI was the second highest cause of transfusion-related morbidity and mortality and the major cause of transfusion-associated mortality.[4] The French Haemovigilance System found TRALI to be responsible for 25% of transfusion-associated fatalities in 2003.[5] Clearly, TRALI represents an important clinical syndrome with the potential for serious recipient adverse outcomes. However, much about the pathogenesis, treatment, and prevention of TRALI is poorly understood or still quite controversial or both.

DEFINITION

The need for a common definition of TRALI has been identified as a priority by the TRALI Working Group convened by the National Heart, Lung, and Blood Institute (NHLBI) of the National Institutes of Health (NIH), the Canadian Consensus Conference (Towards an Understanding of TRALI) sponsored by Canadian Blood Services and Héma-Québec, and authors of recent reviews.[6–12] A universally accepted case definition is crucial for the accurate diagnosis of TRALI, the collection of accurate and reliable epidemiologic data, and the comparison of TRALI reports between centers and countries. Furthermore, the lack of a uniform TRALI definition makes the interpretation of existing data about TRALI problematic because of variations of the TRALI definition used in the reported studies.

The NHLBI Working Group definition of TRALI is "new acute lung injury (ALI) that develops with a clear temporal relationship to transfusion, in patients without or with alternate risk factors for ALI."[9] The NHLBI group used the definition for ALI developed by the North American-European Consensus Conference in 1994 (Table 51–1).[13] Strengths of this definition are that it provides objective criteria for the diagnosis of TRALI and includes consideration of TRALI in patients with risk factors for ALI or acute respiratory distress syndrome (ARDS).[8]

A Canadian Consensus Conference on TRALI, held in Toronto, Canada, in April 2004, was entitled "Towards and Understanding of TRALI," with the goal of providing recommendations about several outstanding issues including the lack of a common definition of TRALI.[7,8] After considering information presented by expert panelists, and a review of relevant literature and deliberation, the following definition of TRALI was proposed by the panel: "a new episode of ALI that occurs during or within 6 hours of a completed transfusion which is not temporally related to a competing etiology for ALI" (Table 51–2).[7] In the development of this definition, TRALI was considered to be a clinical syndrome rather than a disease of a single etiology. Furthermore, the diagnosis of TRALI was considered to be a clinical and radiographic diagnosis, not dependent on the results of laboratory testing or any specific pathophysiologic mechanism.

The Canadian definition represented an adaptation of that suggested by the United States NHLBI Working Group on TRALI.[9] Two main differences between the definitions are first that, in the Canadian definition, the ALI criteria for hypoxemia were expanded to include other clinical evidence of hypoxemia for the purposes of patient care and surveillance studies when pulse oximetry measurements on room air are not available. Second, because of the uncertainty of the relation of ALI to transfusion in instances in which other risk factors for ALI (other than massive transfusion) are present (Table 51–3), the Canadian Consensus Panel recommended the use of the term *possible TRALI*. This was considered important to be able to include the uncertainty of the relationship of the ALI to the transfusion event in possible TRALI, the need to categorize such cases separately in surveillance systems to permit accurate comparisons across systems, the ability to selectively target research protocols to TRALI or possible TRALI cases, and the possible adoption of differing approaches to donor investigation in TRALI versus possible TRALI cases.[7]

The NHLBI Working Group also recognized these problematic cases (e.g., cases of ALI in recipients with recognized ALI risk factors other than massive transfusion) but recommended that critical care experts make the assessment of whether a case of ALI in such a patient is TRALI before reporting it to the blood bank. The NHLBI Working Group recognized that some of these cases would be difficult to classify accurately and proposed the classification of indeterminate for these cases.[9]

Both definitions have limitations, including the exclusion of mild TRALI cases whose clinical symptoms fall short of the case definition, cases in which symptoms develop after 6 hours (which occur rarely), and cases in which TRALI coexists with cardiogenic pulmonary edema.

Table 51–1 Criteria for Diagnosing Acute Lung Injury (ALI). Proposed by the North American-European Consensus Conference on Acute Respiratory Distress Syndrome and Modified by the NHLBI TRALI Working Group

- Acute onset
- No evidence of circulatory overload
  - Pulmonary artery occlusion pressure: <18 mmHg when measured; or
  - Lack of clinical evidence of left atrial hypertension
- Bilateral infiltrates on frontal chest radiograph
- Hypoxemia
  - Ratio of $Pao_2/Fio_2 \leq 300$ mm Hg regardless of positive end-expiratory pressure level; or
  - Oxygen saturation of ≤90% on room air

Modified from Toy P, Popovsky MA, Abraham E, et al. Transfusion-related acute lung injury: Definition and review. Crit Care Med 33:721–726, 2005; Bernard GR, Artigas A, Brigham KL, et al. Report of the American-European Consensus conference on acute respiratory distress syndrome: definitions, mechanisms, relevant outcomes, and clinical trial coordination. Consensus Committee. J Crit Care 1994;9:72–81.

Table 51–2 Canadian Consensus Conference Criteria for TRALI and Possible TRALI

Criteria for *TRALI*

a. ALI
   i. Acute onset
   ii. Hypoxemia
      In research setting
      Ratio of $Pao_2/Fio_2 \leq 300$; or
      $Spo_2 < 90\%$ on room air
      In a nonresearch setting
      Ratio of $Pao_2/Fio_2 \leq 300$ or
      $Spo_2 < 90\%$ on room air; or
      Other clinical evidence of hypoxemia
   iii. Bilateral infiltrates on frontal chest radiograph
   iv. No evidence of left atrial hypertension (i.e., circulatory overload)

b. No pre-existing ALI before transfusion

c. During or within 6 hr of transfusion and

d. No temporal relation to an alternative risk factor for ALI.

Criteria for *possible TRALI*

1. ALI (see above)
2. No pre-existing ALI before transfusion
3. During or within 6 hr of transfusion and
4. A clear temporal relation to an alternative risk factor for ALI

Modified from Kleinman S, Caulfield T, Chan P, et al. Toward an understanding of transfusion-related acute lung injury: Statement of a consensus panel. Transfusion 2004;44:1774–1789.

It was acknowledged by the Canadian TRALI Consensus Panel that its definition of TRALI represented the start to the development of an international consensus definition and would evolve as more data became available from additional surveillance, epidemiologic studies, pathologic evaluations, and research.[7]

EPIDEMIOLOGY

The incidence of TRALI is not well defined but has been estimated to occur between 0.014% and 0.08% per allogeneic blood product unit transfused or 0.04% to 0.16% per patient transfused.[14–18] Furthermore, the incidence rates for various blood products vary widely, with estimates ranging from 1 in 432 to 1 in 88,000 per unit of whole blood platelets, 1 in 1224 per unit of apheresis platelets, 1 in 4000 to 1 in 557,000 per unit of red blood cells (RBCs), and 1 in 7896 to 1 in 74,000 per unit of fresh frozen plasma (FFP) transfused.[7,8,18,19]

In the United Kingdom for the year 2003, 36 cases of TRALI were reported. This represents an increase from the 26 cases reported from October 2001 until September 2002 and an increase from an average of 14 cases per year for the years 1996 through 2000.[4] This trend most likely indicates increasing awareness of the condition. However, it is generally agreed that TRALI is still underdiagnosed and under-reported and that the true incidence of TRALI may be higher than current estimates.[18,20,21] This is likely due in part to a lack of recognition of the condition, in that TRALI can be easily confused with other diagnoses such as ARDS, fluid overload, and congestive heart failure.[21] Furthermore, because TRALI often occurs in patients in poor clinical condition, the respiratory distress of TRALI may be attributed to the underlying clinical condition and not to the allogeneic transfusion.

The risk factors that contribute to the development of TRALI are unknown. Cases of TRALI have occurred in all age groups and appear to be distributed evenly among male and female patients.[8,17,22] Most TRALI patients have no history of transfusion reactions, and no specific diagnoses are clearly associated with increased risk for TRALI.[17] It has been suggested that certain clinical conditions are associated with an increased risk. These include thrombotic thrombocytopenic purpura (TTP), organ transplantation, hematologic malignancy, and various cardiac diseases.[23–27] Although many TRALI cases appear to occur in patients in poor clinical condition at the time of the administration of implicated transfusion,[28] TRALI has been documented to occur in otherwise healthy subjects.[21,29]

Most blood components, including whole blood, RBCs, platelets, FFP, cryoprecipitate, intravenous immunoglobulin (IVIG), allogeneic bone marrow, autologous RBCs, and granulocyte concentrates have been implicated in the

Table 51–3 Risk Factors for Acute Lung Injury (ALI)

- Direct lung injury
  - Aspiration
  - Pneumonia
  - Toxic inhalation
  - Lung contusion
  - Near drowning
- Indirect lung injury
  - Severe sepsis
  - Shock
  - Multiple trauma
  - Burn injury
  - Acute pancreatitis
  - Cardiopulmonary bypass
  - Drug overdose

Note: Although massive transfusion (i.e., one blood volume in a 12- to 24-hr period) is also a recognized risk factor for ALI, it has been excluded from this list because ALI occurring within 6 hr of any transfusion (including massive transfusion) is considered to be TRALI.

Modified from Kleinman S, Caulfield T, Chan P, et al. Toward an understanding of transfusion-related acute lung injury: Statement of a consensus panel. Transfusion 2004;44:1774–1789.

pathogenesis of TRALI.[17,22,30–35] FFP is the most frequently implicated blood product.[22] In most reported cases of TRALI, the implicated blood product usually has contained more than 60 mL of plasma; however, cases of TRALI have occurred after the transfusion of products containing less than 60 mL of plasma, such as cryoprecipitate and platelet concentrates.[20] The severity of TRALI appears not to be related to the type of blood product transfused. The relation to antibody specificity has not been well studied, but several case reports suggest that antibodies against one specific neutrophil antigen, HNA-3a (5b), may be more prone to cause severe TRALI reactions.[36] It has been claimed that TRALI incidence may be increased with the administration of older components. However, the only evidence to support this claim is a study by Silliman and colleagues,[18] in which implicated whole blood–derived platelet units were only slightly older than nonimplicated units (4.5 + 0.2 days vs. 4.2 + 0.1 days; $P = 0.014$).

CLINICAL PRESENTATION AND LABORATORY INVESTIGATIONS

TRALI is clinically indistinguishable from acute lung injury due to a variety of causes.[16] The clinical manifestations of TRALI typically begin within 6 hours of a transfusion, and most cases occur during or within 2 hours of transfusion.[14] The symptoms and signs of TRALI typically include acute respiratory distress, severe hypoxemia, hypotension, and fever (Table 51–4). The hypotension is frequently unresponsive to the administration of intravenous fluids.[20] Less typically, hypertension may be present. The physical examination is usually consistent with noncardiogenic pulmonary edema. Rales and diminished breath sounds are usually present without other evidence of fluid overload (normal jugular venous pressure or absent third heart sound or both). Radiographic investigations typically reveal bilateral pulmonary infiltrates consistent with pulmonary edema. The infiltrates are usually both alveolar and interstitial and involve both lung fields; however, initially the radiographic pattern may be that of a patchy infiltrate.[20] It has been noted that a discrepancy may exist between the severity of the radiographic findings and the auscultatory findings.[14,37] The pulmonary wedge pressure is almost invariably normal.

Because the diagnosis of ALI can be difficult, when a case of TRALI is reported from the hospital ward to the blood bank, it is important for the blood bank medical director to communicate with the attending physician to determine whether that case has a high probability of increased left atrial pressure. If so, the pulmonary edema is more likely cardiogenic pulmonary edema, rather than ALI.

With the current proposed definitions of TRALI, milder acute lung injury caused by transfusion will not be diagnosed as TRALI. However, data indicate that such cases do exist, but do not meet the proposed definition of TRALI.[20] For example, in a look-back investigation, approximately half of the symptomatic cases identified retrospectively involved findings of dyspnea and hypoxia without evidence of pulmonary edema.[15] The European Hemovigilance Network has proposed classifying such cases as *transfusion-associated dyspnea* to ensure that such cases are tabulated in transfusion-surveillance systems.

Patient laboratory findings of TRALI may include transient leucopenia, neutropenia, monocytopenia, and hypocomplementemia.[8,38] Additional laboratory studies performed on donor blood or the transfused blood component may elicit data that are useful to help classify the mechanism of TRALI (e.g., leukoagglutinating or leukocytotoxic antibodies or both in the donor, high levels of active lipids in the donor plasma, and neutrophil-priming activity in the blood component or post-transfusion donor and patient plasma).[8] These laboratory findings should not be used to make the diagnosis of TRALI, which is currently a clinical and radiographic diagnosis.

Table 51–4 Symptoms Associated with Transplant-Associated Acute Long Injury

Symptom/Sign	Relative Frequency
Dyspnea, respiratory distress	Very common
Hypoxia	Very common
Pulmonary edema	Very common
Fever (1°C to 2°C increase)	Very common
Tachycardia	Common
Hypotension	Common
Cyanosis	Common
Hypertension	Rare

PATHOPHYSIOLOGY OF TRALI

The exact pathophysiologic mechanisms of TRALI have not been clearly elucidated. Both immunologic and nonimmunologic mechanisms have been suggested. It is likely that the mechanism of TRALI pathogenesis may vary from patient to patient, representing a spectrum including immunologic mechanisms, nonimmunologic mechanisms, or a combination of both. Regardless of the initiating mechanism, it appears that biologically active molecules (for example, cytokines and antibodies) affect (activate) leukocytes, leading to pulmonary endothelial cell injury and pulmonary edema, which appears to be the common final pathophysiologic pathway in the pathogenesis of TRALI.

Immunologic Mechanisms

Most investigators have postulated that TRALI is an antibody-mediated event.[15,21,39] In the first reported large case series of 36 cases of TRALI, 89% of donors had HLA or leukoagglutinating alloantibodies, with antibody/antigen concordance between donor and recipient demonstrated in 59% of cases.[14]

The alloantibodies thought to be responsible for TRALI have been identified as antineutrophil or anti-human leukocyte antigen (anti-HLA) class I or class II antibodies.[14,15,21,26,40–49] The mechanism of TRALI caused by HLA class II antibodies may differ from that associated with neutrophil and HLA class I antibodies in that resting neutrophils do not express HLA class II antigens. Occasional reports of TRALI have been associated with antilymphocyte, antimonocyte, or anti-immunoglobulin alloantibodies.[15,21,50–54] The specific neutrophil alloantigens that have been implicated in TRALI episodes include HNA-1a (NA1); HNA-1b (NA2); HNA-3a (5b); and HNA-2a (NB1).[29,40,55–59]

The pathogenic alloantibodies are typically of donor origin[21,39] but in fewer than 10% of cases, the alloantibodies

may be of recipient origin directed against donor-specific leukocyte alloantigens.[21,40] Blood donors most commonly implicated in TRALI are multiparous women in whom maternal alloantibody formation occurred after exposure to paternally derived alloantigens on the fetal white blood cells entering the maternal circulation during pregnancy. Donors who had previously been transfused may also have formed such alloantibodies.

The immunologic mechanism postulates that donor alloantibodies in the transfused blood product interact with the recipient's leukocyte (usually neutrophil) antigens, leading to activation of the complement cascade, mobilization of cytokines, or priming of neutrophils. Although the initiating antigen-antibody interaction is generally thought to involve neutrophil alloantigens, the initial interaction may also occur between antibodies and monocyte or endothelial cell alloantigens.[15] This antigen-antibody interaction could also lead to the production of activated complement components, such as C5a, possibly resulting in pulmonary leukostasis and activation of white blood cells.[60] Alternately, antibody-antigen complexes may activate neutrophils through one of the Fc receptors (CD16, CD32, CD64). The activation of neutrophils then could result in the production of inflammatory mediators to cause increased vascular permeability,[39] leading to capillary leak and pulmonary tissue damage.[14,61] Some experimental evidence supports this hypothesis. For example, the infusion of leukoagglutinating antibodies in humans has been shown to cause the localization of granulocytes in the pulmonary circulation.[62] Furthermore, in animal models, these alloantibodies have been demonstrated to cause acute pulmonary edema in the presence of a complement source.[63] The sequestration of neutrophils has been demonstrated to occur only in the lungs; however, it is possible that accumulations of granulocytes also occur in other organs; but no clinical evidence exists that other organs are damaged in patients with TRALI.

The ability of transfused HLA alloantibodies to induce TRALI reactions was elegantly illustrated in a case report of a patient who had previously undergone a single lung transplant.[64] The patient developed TRALI after the transfusion of a unit of packed RBCs, which was subsequently demonstrated to contain antibodies to HLA-B44. The lung injury occurred only in the patient's transplanted lung, which expressed the HLA-B44 antigen on endothelial cells, and not in the native lung, which was HLA-B44 negative.

Nonimmunologic Mechanisms

Antigranulocyte or anti-HLA antibodies or both have been reported to be present in the majority of TRALI cases, in up to 89% of cases in one case series.[17] However, in at least 15% of typical cases of TRALI, antibodies are not detected in either the recipient or the donor.[65] Some investigators have found this latter number to be much higher.[18,28] For example, in a recent prospective study by Silliman and colleagues[18] an anti-HLA or antigranulocyte antibody was found in the donor plasma in only 25% of TRALI cases, and only 3.6% of TRALI cases had an antibody with definable specificity. Furthermore, in the same study, control cases without a diagnosis of TRALI were just as likely to have been transfused an allogeneic blood component from a donor with an antileukocyte antibody as were those patients who developed TRALI.[18] This may be explained either (1) by the fact that the responsible antibodies were of an unknown specificity; (2) that the antibodies were sequestered within immune complexes fixed to pulmonary tissue and were therefore not detectable in the circulation; (3) the antibodies were HLA class I but were not complement binding or present in a low titer and were missed by the standard lymphocytotoxicity assays[57]; or (4) that some other factor was involved.[66] The authors concluded that their findings were consistent with an alternate hypothesis—that the pathogenesis of TRALI may be non–antibody mediated. Suggested mechanisms postulated by these investigators include the generation of biologically active lipids, or the interleukins (IL)-6 or -8, present in increased concentrations in stored cellular blood products.[18,66,67]

Two-Event Model

It has been hypothesized that many TRALI cases are the result of two insults, the first related to the underlying clinical condition of the patient, and the second, to the infusion of biologic response modifiers within the blood component transfused.[18,54] Severe TRALI is clinically very similar to ARDS, and it has been demonstrated in animal models that the development of ARDS requires at least two pulmonary insults.[68,69] Similarly, it has been hypothesized that two events are required to produce clinical evidence of TRALI: the first being a predisposing clinical condition, such as surgery, trauma, or severe infection, and the second being the transfusion of biologically active lipids, cytokines, or leukoagglutinating alloantibodies in the blood product transfused.[28] This mechanism postulates that the first event results in activation of the pulmonary endothelium, which causes a release of cytokines and an increase in the number of adhesion molecules expressed on the endothelial cell surface.[1] As a result, neutrophils are primed for their subsequent attraction and adherence to the endothelial surface. The second event then results in neutrophil activation and release of substances leading to pulmonary damage as well as capillary leakage.[1,69,70]

Cytokines that may be involved in the pathogenesis of TRALI include tumor necrosis factor (TNF)-α, IL-1, IL-6, and IL-8.[18,39] Silliman and colleagues[18,28,71–74] have demonstrated that the occurrence of TRALI is associated with the transfusion of certain types of lipids with neutrophil-priming activity. These lipids have been identified mainly as lysophosphatidyl cholines, demonstrated to accumulate in cellular blood products with prolonged storage.[18] It is unlikely, however, that such biologically active lipids are responsible for all cases of TRALI, as they have not been demonstrated to be in FFP, even though the transfusion of FFP has been linked to many cases of TRALI.[15,43,47]

Animal Models of TRALI

Information about the pathogenesis of TRALI has been obtained through studies in animal models of TRALI or acute lung injury. These models are described in greater detail in a recent review.[75]

The first animal model of TRALI was described by Seeger and associates.[76] In this model, ex vivo isolated rabbit lungs were perfused with albumin buffer with HNA-3a–positive human granulocytes added. The presence of an antibody with HNA-3a specificity, with rabbit plasma as a complement source, caused severe pulmonary edema within 3 to 6 hours associated with increased lung vascular permeability. No pulmonary edema occurred in the absence of anti–HNA-3a antibody, HNA-3a–positive neutrophils, or rabbit plasma. Vascular permeability was also not increased when

HNA-3a–negative neutrophils were used. These experiments corroborated the role of leukoagglutinating antibodies in initiating neutrophil-dependent lung injury and suggested that concomitant complement activation played a role in its pathogenesis.

Sachs and colleagues[77] recently published studies using a similar ex vivo rat lung model of TRALI. Their experiments demonstrated that the induction of TRALI by antileukocyte antibodies was dependent on the density of the cognate antigen. However, the induction of TRALI did not require the addition of complement. Furthermore, the anti–HNA-2a antibodies used in this model did not induce leukoagglutination. The authors thus concluded that TRALI does not necessarily require either the leukoagglutinating properties of the antibody or the presence of complement proteins. The authors hypothesized that antibody-mediated neutrophil activation and the subsequent release of reactive oxygen species represent key events in the pathophysiologic cascade that leads to some cases of immune TRALI.

Silliman and colleagues[73] also described an ex vivo two-event model of TRALI. In this model, rats were pretreated with endotoxin in vivo. Isolated lungs were then perfused with saline, fresh human plasma, stored human plasma, lipid extracts from stored human plasma, or purified lysophosphatidyl cholines. Lungs pretreated with endotoxin developed significant pulmonary edema when perfused with stored plasma, lipid extracts, or lysophosphatidylcholines. Similar results were obtained in subsequent studies when the lungs were perfused with plasma from stored platelet concentrates.[78] This model demonstrated that biologically active lipids, which may be produced during the storage of blood products, can cause acute lung injury in a two-step fashion.

DIAGNOSIS OF TRALI

No rapid or conclusive test exists with which to diagnose TRALI. The initial diagnosis of TRALI should be suspected if a blood-product recipient has appropriate clinical findings (acute onset of hypoxemia, as demonstrated by a ratio of Pao_2/Fio_2 less than 300 mm Hg or an oxygen saturation less than or equal to 90% on room air with no evidence of circulatory overload) within 6 hours of a transfusion, together with the exclusion of other causes of pulmonary edema. The clinical findings should be corroborated with a radiograph of the chest demonstrating bilateral infiltrates. It is particularly important to exclude pulmonary edema secondary to cardiac causes, or volume overload, as these latter conditions are managed very differently from TRALI. It has been suggested that the determination of brain-derived natriuretic peptide (BNP) levels may help to differentiate TRALI and the volume overload observed in congestive heart failure (CHF), as elevated levels of BNP are highly predictive of CHF.[79] This interesting hypothesis requires further study and confirmation.

After the urgent management of the TRALI patient, laboratory investigations may be performed to gather information to support the antibody-mediated mechanism of TRALI. In the majority of cases in most published series, the donor plasma has been found to contain anti-HLA or antineutrophil antibodies or both.[17] Rarely, the recipient may be shown to have antibodies reactive with antigens on donor neutrophils.[17,42] As the diagnosis of TRALI in the past has typically required the presence of recipient-specific antibodies in the donor plasma, TRALI cases not associated with alloantibodies may have been underdiagnosed. Although not required for the diagnosis of TRALI, investigation of associated donors for the presence of anti-HLA class I and class II and antineutrophil antibodies may be performed to guide donor management.

TREATMENT

The treatment of TRALI is primarily supportive. The patient's hemodynamic status should be maintained. Ventilatory supportive care may be required, which may include oxygenation, intubation, and even mechanical ventilation.[17,66] In the original case series, all patients with TRALI required supplemental oxygen, and more than 70% of patients required mechanical ventilation.[8] Vasopressor medications may be necessary to treat the hypotension as TRALI patients are usually unresponsive to the infusion of fluids. Diuretics should not be used.[20] Treatments that have been suggested, but which have no established direct benefit, include the use of corticosteroids, prostaglandin E_1, anti-endotoxin antibodies, nonsteroidal anti-inflammatory medications, anti-TNF antibodies, pentoxiphylline, and surfactant.[21,80] However, practices and recommendations among transfusion medicine experts vary. A recent case report describes the successful use of extracorporeal membrane oxygenation (ECMO) for the treatment of TRALI in a 4-year-old patient undergoing elective cardiac surgery.[81] The authors recommended that, where facilities exist, ECMO or cardiopulmonary bypass should be considered in the management of severe TRALI when conventional treatment is proving insufficient. It is important to point out that if TRALI is suspected during the transfusion of a blood product, the transfusion should be immediately discontinued.

PROGNOSIS

TRALI patients generally improve clinically within 48 to 96 hours of onset.[17] Usually a resolution of the pulmonary infiltrates, as assessed by chest radiographs, occurs within 1 to 4 days.[17,30] However, in approximately 20% of patients, the hypoxemia and pulmonary infiltrates may persist for longer than 7 days. In those patients who recover rapidly, no long-term sequelae are found.[17]

Despite the usually excellent prognosis, it should be noted that TRALI can be a serious condition. TRALI is fatal in 5% to 10% of reported cases.[14,17,21,82] It is one of the top three causes of transfusion-related mortality.[3,8,27,83] TRALI has been suspected or confirmed in more than 10% of fatalities related to transfusion reported to the FDA from 1997 to 2000 and more than 13% of the fatalities reported to the FDA in 2003.[22] The SHOT Annual Report for 2003 found that TRALI was the major cause of transfusion-associated mortality in Great Britain over a 6-year period.[4] In France, TRALI was reported to have been responsible for 25% of transfusion-associated fatalities in 2003.[5]

EVALUATION OF DONORS ASSOCIATED WITH TRALI

In 2005, the AABB issued a TRALI-related interim standard (Standard 5.4.2.1) to supplement Standards for Blood Banks

and Transfusion Services (23rd edition).[84] The standard states that "donors implicated in TRALI or associated with multiple events of TRALI shall be evaluated regarding their continued eligibility to donate."[85] As per the recommendations of the Canadian Consensus Conference, "associated" and "implicated" donors were defined as follows:

- A donor is *associated* with a TRALI reaction if one of his or her blood components was transfused during the 6 hours preceding the first clinical manifestation of TRALI.
- An associated donor is *implicated* in TRALI only if found to have antibodies to an HLA class I or II antigen or HNA and either that antibody has specificity for an antigen present on the recipient's leukocytes or a positive reaction is demonstrated between donor serum and recipient leukocytes (i.e., a positive crossmatch).

In cases of suspected TRALI, all allogeneic blood components transfused to the patient within 6 hours of the reaction should be examined.[17] Samples of donor plasma should be tested for HLA-I and -II and neutrophil antibodies. It has been suggested that one may increase efficiency by checking donors at greatest risk of having antibodies first, for example, women with three or more pregnancies. However, in one series of cases reported to the FDA, some male donors were found to be positive for anti-HLA antibodies. This suggests that, if sequential donor testing is performed, male donors should be tested if no implicated female donors are identified.[22] Other proposed strategies to increase efficiency of testing include (1) the sequential testing of donors beginning with the testing of donors whose components were administered closest to the onset of the TRALI reaction; and (2) the sequential testing of donors of plasma, platelets, cryoprecipitate, and RBCs, in that order. These strategies may decrease the need to test all donors associated with a TRALI case, as donor testing may be discontinued once an implicated donor has been identified. It should be noted that using any one of these approaches to donor testing will not eliminate the need for the testing of all donors.

If an antibody is found, its specificity should be determined, and it should be determined whether it reacts with the recipient's leukocyte (HNA and HLA) antigens either by performing antigen typing of the recipient's cells or by crossmatching donor sera with recipient cells. The clinical diagnosis of TRALI is strongly supported if concordance is found. However, even if the antibody is not reactive against the recipient's leukocytes, the presence of such alloantibodies is considered by some to be strong presumptive evidence of TRALI, as up to 40% of cases do not actually show concordance.[17] The method of diagnosis described here will result only in the identification of donors in cases of TRALI caused by the antibody-mediated mechanism but will be negative in many cases of TRALI.[18] Ideally, consideration should be given to the investigation of the implicated products or post-transfusion recipient specimens or both for neutrophil-priming agents in addition to testing donors for alloantibodies. However, currently, the testing for neutrophil priming is not readily available and at this time involves testing the respiratory burst to a specific stimulus.

MANAGEMENT OF FUTURE TRANSFUSIONS IN PATIENTS WITH A HISTORY OF TRALI

As mentioned previously, in a minority of TRALI cases, an implicated alloantibody is found in the recipient. Therefore, the possibility exists that an individual who has had TRALI in the past is at increased risk for a second (recurrent) TRALI reaction with subsequent transfusions. The care of these recipients has not been well addressed in the literature. As with any patient, the judicious use of allogeneic blood products is mandatory. It is reasonable to monitor closely patients with a history of TRALI during and after the subsequent transfusion of allogeneic blood products. It has been suggested that repeated TRALI reactions in these patients may be prevented by leukoreduction of any cellular components transfused to a TRALI patient; however, no evidence supports or refutes this practice.[20]

PREVENTION OF TRALI

Because of the multiple etiologies proposed for TRALI and the previously variable criteria for diagnosis, clear recommendations for the prevention of TRALI do not presently exist.[59] Various suggestions have been made and are discussed.

Deferral of All Implicated Donors

A general consensus exists that blood donors with demonstrable antibodies, who have been implicated in TRALI reactions, should be permanently deferred.[7,8] This is a reasonable approach, as at least two studies have suggested that donors with a leukocyte alloantibody who are implicated in a case of TRALI may represent a future transfusion hazard.[26,86] In the first study, the authors investigated all donations made by an implicated donor with alloantibodies to the HNA-3a antigen in the preceding 2 years.[82] Of the 36 patient charts evaluated, 36% of recipients had symptoms suggestive that a transfusion reaction had occurred. In the second look-back study, 15% of all donations of a donor with high-titer, leukocytotoxic class I HLA alloantibodies implicated in TRALI in a 3-year period were associated with a recorded transfusion reaction.[26] In contrast to these two studies, a look-back study performed by Win and colleagues[87] demonstrated that infusion of blood products containing leukocyte antibodies that appeared to have caused TRALI in some patients did not necessarily result in TRALI in other recipients. When the transfusion records of 43 blood components collected from six donors with alloantibodies implicated in cases of TRALI were reviewed, no documentation of transfusion reactions was found in any of the recipients of previous blood products from these donors. Similarly, Toy and associates[88] examined the records of patients who received blood components from a donor subsequently implicated in a TRALI reaction and found to have multiple HLA antibodies directed at both class I (A1, A2, A23, A24, A28, B35, Bw4) and class II (DR4, DR7, DR11, DR12, and DQ5) antigens.[88] Among the 103 patients reviewed, only one had evidence of a reaction that met criteria for TRALI, but on further review, this patient was diagnosed as having diffuse alveolar hemorrhage secondary to a stem cell transplant. Of the 55 recipients who had HLA-typing results available, none developed TRALI, even though 54 (98%) of the recipients had at least one corresponding antigen. The results of the latter two studies indicate that the deferral of all implicated donors will result in the deferral of some donors with antibodies with common specificities that may not have caused the TRALI reaction in the first instance.[7]

It is less clear what should be done with donors who are found to have antibody that does not correspond to a

recipient antigen. Some authorities would recommend deferring such donors; however, as many blood donors with anti-HLA antibodies are never implicated in TRALI reactions, this approach is probably not necessary. A third possible outcome of a donor investigation is that none of the donors is found to have HLA or neutrophil alloantibodies. This is the case in at least 15% of TRALI cases in the literature.[18,31,39] No evidence exists that these antibody-negative donors are associated with an increased risk of future episodes of TRALI. The TRALI Consensus Panel and the AABB have suggested that it would be reasonable for such individuals to continue to donate.[7,85]

Rather than deferring donors whose blood products were implicated in TRALI, another option would be to use the blood products as frozen deglycerolized or washed RBCs from these donors only in special circumstances (i.e., rare donors).

Deferral of All Multiparous Women

The suggestion that all multiparous women should be deferred from donating blood is controversial. Donors implicated in TRALI reactions are often multiparous women or women who have had at least three live births.[20] In female blood donors, the frequency of anti-HLA antibodies has been demonstrated to increase with the number of pregnancies, ranging from 7.8% in nulliparous women to 26.3% in women who have had three or more pregnancies.[89] A recent study of female platelet donors demonstrated 12.9% to be positive for either HLA class I or class II antibodies.[48]

To investigate the clinical and immunologic outcomes after the transfusion of plasma from multiparous donors, Palfi and colleagues[90] performed a prospective randomized study. Patients in the intensive care unit receiving plasma were randomized to receive 1 unit of plasma from a multiparous donor and 1 unit of control plasma in a random order. The transfusion of plasma from multiparous donors was found to be associated with significantly lower oxygen saturation and higher TNF-α concentrations in the recipients compared with that seen in recipients after transfusion of control plasma. Furthermore, the mean arterial pressure increased after the transfusion of control plasma but did not change after the infusion of multiparous donor plasma. Finally, five post-transfusion reactions were observed in 100 patients, in four cases after the transfusion of plasma from multiparous donors, and in one after the transfusion of control plasma. These investigators concluded that plasma from multiparous blood donors may impair respiratory function in critically ill patients and should not be used in such patients. Clearly, further studies are required to evaluate the clinical effects of plasma from multiparous donors in other patient groups.

As TRALI is a serious, potentially fatal, condition whose frequency could be diminished by the deferral of multiparous donors, this approach has been debated.[17] However, the deferral of multiparous donors would result in a substantial reduction in the donor pool. For example, approximately one third of apheresis donors in a representative hospital apheresis program in the United States would be affected by such a policy.[89] Furthermore, it has been estimated that the use of this strategy by America's Blood Centers (ABC) members and the American Red Cross would result in the loss of 550,000 donations annually in the United States.[91] Thus as some have argued, because TRALI is a rare condition, it may be reasonable to use a more moderate approach with the deferral of only donors actually implicated in TRALI cases.[2,66] This issue is further complicated by the fact that recent prospective studies have not identified antileukocyte antibodies as a major pathogenic mechanism of TRALI.[18]

Use of Plasma from Multiparous Women Only for Fractionation

Some investigators have suggested that blood from multiparous donors who have not been screened for leukocyte alloantibodies should not be used as whole blood, FFP, or single-donor apheresis platelets.[8,17] It is uncertain whether blood products that do not contain significant amounts of plasma (such as RBCs stored in protein-poor solutions and cryoprecipitate) should be used. The transfusion of a small volume of plasma would, theoretically, carry a reduced risk of an alloantibody-mediated reaction,[17] and TRALI has been reported infrequently after the transfusion of these products.[54,92] It is generally agreed that such donors could serve as a safe source of plasma for fractionation, and as a source of frozen-deglycerolized RBCs or washed RBCs.[17] To decrease the risk of TRALI, in 2003, the National Blood Services in the United Kingdom decided not to use plasma from female donors (regardless of parity for logistic considerations) for FFP production. Since the implementation of this policy in England, more that 90% of the FFP available is now derived from male donors.[8] The potential efficacy of this initiative in reducing TRALI risk likely will be not be evaluable for several years.

Screening of All Donors (or Just Multiparous Women) for Antineutrophil and Anti-HLA Antibodies

At least one blood bank has used a preventive strategy that involves the screening of all donors for leukocyte antibodies. Those donors that are identified as having leukocyte alloantibodies are excluded from donating, or their blood is only used for blood products that do not contain significant amounts of plasma or that are fractionated.[21] This approach has been questioned, as HLA antibodies are present in many donors; most do not cause TRALI reactions.[60] In a recent study, HLA alloantibodies were found to be present in 22% of blood components tested.[93] Furthermore, this screening method would not prevent cases of TRALI caused by nonimmunologic mechanisms or those associated with alloantibodies in the recipient.

Use of Prestorage Leukoreduced Red Blood Cells

The use of leukoreduced blood components may result in decreased risk of TRALI.[94] This theory is based on the fact that animal experiments have demonstrated complement activation to have a role in initiating TRALI[63] and that leukoreduction prevents complement-mediated hemolysis in transfused patients with paroxysmal nocturnal hemoglobinuria. Further clinical data are required to confirm whether this intervention actually decreases the risk of TRALI.

Use of Younger Blood Products

One group of investigators has suggested that, in contrast to the generally accepted theories, the role of antileukocyte

antibodies in the pathogenesis of TRALI is minor and that biologically active lipids and cytokines with neutrophil-priming activity may play a greater role.[18] If this is the case, the majority of cases of TRALI will not be prevented by excluding donors with anti-HLA antibodies. Preventive measures would also need to include measures to decrease the amount of neutrophil-priming agents in blood components. As biologically active lipids accumulate in blood products with storage, it has been suggested that the administration of fresh cellular components would reduce the risk of TRALI by preventing exposure of recipient neutrophils to neutrophil-priming agents.[8,18,90] However, it has been demonstrated that units of blood components implicated in TRALI have higher lipid priming activity than control units of similar storage age.[18] This finding suggests that factors other than the age of the blood product contribute to the risk of TRALI and that further study is needed before age of blood components can be used to mitigate the risk of TRALI.[66]

Appropriate Utilization of Blood Products

A simple way of decreasing the frequency of TRALI reactions is to ensure that blood products are used only when clinically indicated. Reduction of blood product utilization, by using evidence-based criteria for transfusion, may be a safe and appropriate strategy to decrease the incidence of TRALI.[7,95]

Use of Solvent/Detergent Plasma

To date, solvent/detergent (SD) plasma transfusion has not been implicated in TRALI cases. However, it is unclear whether countries that use a large amount of SD plasma have sufficiently sensitive transfusion-surveillance systems to detect these cases should they occur. It has been hypothesized that the use of SD plasma instead of FFP may decrease the risk of TRALI as a result of the plasma-pooling process, decreasing the titer of responsible antibodies.[7] However, it is also theoretically possible that an antibody could cause TRALI despite its dilution by pooling.

Other Possible Interventions

Reports have been published of TRALI occurring in children as a result of directed donations from their mothers.[96–98] As mothers may have developed alloantibodies to antigens on fetal leukocytes during the pregnancy, this, theoretically, represents a situation potentially associated with an increased risk of TRALI. TRALI should be recognized as a potential, serious consequence of directed maternal blood donation.[39]

CONCLUSIONS

TRALI is a complex clinical syndrome that probably does not represent a single pathogenic entity. The ability to define and accurately diagnose TRALI has been hampered by our poor understanding of the pathophysiologic mechanisms of TRALI. Thus the recent recognition that TRALI likely represents a spectrum of clinical presentations and the creation of a standardized TRALI definition represent potential progress in our awareness of this perplexing syndrome. Many unanswered questions and controversial issues are related to our knowledge of TRALI. Many of these issues were addressed by the recent Canadian Consensus Conference.[7,8] However, despite the outstanding job that was done by presenters at the conference and by the Consensus Conference Panel, some issues still remain unresolved.

Traditionally, the definition of TRALI has required the presence of donor leukocyte antibodies reactive against the recipient's leukocytes. However, as our understanding of TRALI has grown, it has become increasingly recognized that not all cases of TRALI are associated with antileukocyte antibodies. It has been hypothesized that such cases may involve antibodies against other antigens, antibodies of recipient origin, or pathophysiologic mechanisms of TRALI not previously recognized.[18]

One of the most urgent needs for the transfusion medicine community is to achieve consensus on a classification for TRALI. In the interest of initiating such discussions, a proposed pathophysiological classification of TRALI is shown in Table 51–5. In this classification, TRALI is classified by the pathogenic mechanism identified. It is recognized that overlap may occur, with both immunologic and nonimmunologic mechanisms occurring in the same episode of TRALI.

Finally, although TRALI is becoming increasingly well recognized by hematologists and transfusionists, it is necessary to educate physicians in all medical specialties and other health care personnel to recognize promptly and to respond appropriately to the signs and symptoms of TRALI.

Table 51–5 Proposed Classification of TRALI Based on Putative Pathogenic Mechanisms

The pathogenesis of transplant-associated acute lung injury (TRALI) reactions is complex and likely varies from patient to patient, thus representing a spectrum including immunologic mechanisms, nonimmunologic mechanisms, or a combination of both. Thus the categories listed below are not mutually exclusive. Many TRALI episodes thus may fall into two or more categories within this proposed classification.

A. Immunologic mechanism indicated
   1. Donor alloantibodies detected
      a. Concordance demonstrated (reactive against recipient antigens)
      b. Concordance not demonstrated (not reactive against recipient antigens)
   2. Recipient alloantibodies detected
      a. Concordance demonstrated (reactive against donor antigens)
      b. Concordance not demonstrated (not reactive against donor antigens)

B. Nonimmunologic mechanism indicated
   3. Predisposing clinical condition in the patient
      a. Surgery
      b. Trauma
      c. Severe infection
      d. Thrombotic thrombocytopenic purpura
      e. Other
   4. Nonimmune biologic response modifiers (BRMs) present in donor product
      a. Biologically active lipids
      b. Cytokines

   Other BRMs

Chapter 52

Transfusion-Related Immunomodulation

Neil Blumberg • Joanna M. Heal

INTRODUCTION

In recent years, a more conservative approach to blood transfusion has begun to become the rule rather than the exception in clinical medicine. To a significant degree, this is the result of clinical outcomes research demonstrating that patients receiving traditional allogeneic transfusions (nonleukoreduced, nonautologous red cells) have dramatically higher rates of morbidity and mortality than do similar patients not receiving transfusions. When patients receiving a traditional therapy are shown to do much worse than those not receiving the therapy, an understandable controversy and growing reluctance exist to use that therapy. To an unknown but probably substantial degree, these inferior clinical outcomes are mediated by a complex phenomenon that has been termed *transfusion-related immunomodulation* or TRIM. Paradoxically, TRIM is now known to involve both downregulated cellular immunity and upregulated, inappropriate inflammatory responses.

Transfusion has long been known to affect the immune system. Humoral immunization to red cell alloantigens after transfusion was recognized as a cause of hemolytic disease of the newborn and hemolytic transfusion reactions in the early 20th century. Over the last 20 years, it has become apparent that transfusion also produces clinically significant immunomodulatory effects on cellular immunity.[1,2] Modulation of cellular immunity by allogeneic transfusion may be of importance equal to or greater than that of humoral allosensitization in certain clinical settings, specifically oncology, surgery, and critical care.[1,2] Unfortunately, recent reviews of transfusion immunology often fail to address this subject because of its contentious nature, and, perhaps, a reluctance to challenge long-standing clinical practices that have been in use for most of a century.[1–7]

The insight that transfusions modulate cellular immunity originated with observations in the late 1960s and early 1970s that blood transfusions reduced the rejection rate for cadaveric renal allografts.[8] A decade later, the controversial observation was made that transfusion at the time of cancer surgery is associated with increased tumor recurrence.[9,10] Tartter and colleagues[11] also reported that the incidence of postoperative infections increased in a dose-dependent fashion after perioperative transfusions. Viral infection and autoimmune disorders may be modulated by transfusion,[1] and a modest but reproducible benefit of transfusions is found in women with repetitive spontaneous abortion during pregnancy.[12] Finally, animal models[13,14] and some, but not all, randomized clinical trials[15–18] demonstrate that leukoreduction and autologous transfusion[19] can reduce the immunomodulatory effects of transfusion and minimize resulting morbidity and mortality. Many detailed reviews of TRIM have been published, and the reader is referred to these for summaries of the historical literature.[1,3–7]

TRANSFUSION AND HUMORAL ALLOSENSITIZATION

It has long been known that transfusion or pregnancy can cause formation of clinically significant antibodies to cellular and plasma components of allogeneic blood. Most blood-transfusion research in the first part of the 20th century was focused on techniques for detecting antibody formation and avoiding transfusion of incompatible red cells. Until the late 1960s and early 1970s, the accepted paradigm was that transfusion stimulated the recipient's immune system to make humoral immune responses, and that this was virtually the only immunologic complication of transfusions. Two decades later, it became clear that some antigens, when given intravenously in high dose, can promote a type 2 (primarily humoral) immune response while downregulating type 1 (primarily cellular) responses.[20–22] Approximately 1% to 5% of individuals receiving ABO and Rh(D) identical transfusions or who become pregnant with an Rh-compatible fetus will mount a humoral immune response to red cell alloantigens. About 50% of patients transfused with cellular blood components or who become pregnant will mount a humoral immune response to human leukocyte antigen (HLA)-A,B antigens present on white blood cells (WBCs). Interestingly, in experimental models when antigens are administered at higher doses, in the absence of costimulatory inflammatory "danger" signals, immune tolerance rather than immunization can occur.[23]

By 1990, leukoreduction was found to abrogate post-transfusion humoral responses to white cell antigens (primarily antibodies to HLA class I). Filtering out most (at least 99.9%) of the donor white cells before transfusion is effective at preventing 90% or more of HLA antibody sensitizations in patients undergoing myeloablative chemotherapy and transfusion.[24] Because HLA antibody formation is the primary mechanism of alloimmune platelet transfusion refractoriness, as platelets carry class I antigens, the incidence of unresponsiveness to platelet transfusions due to allosensitization decreased by an order of magnitude, from approximately 50% to 5% or less, after the introduction of filtered, white cell–reduced transfusions.[25] It is possible that leukocyte removal by filtration also decreases the allosensitization rate to red cell alloantigens.[26] One plausible mechanism is that white cell removal decreases the type 2 immune

stimulus that accompanies transfusion of allogeneic white cells. Purified red cells and platelets are known to be less immunogenic than allogeneic white cells. In the absence of allogeneic WBCs, purified red cell components in particular may be less likely to provide inflammatory mediators and costimulatory molecules that activate the recipient's immune system.

TRANSFUSION AND SOLID ORGAN TRANSPLANTATION

More than half a century ago, Billingham, Brent, and Medawar[27] demonstrated that administration of allogeneic antigen to fetal animals resulted in immunologic tolerance. The science, if not the clinical art, of solid organ transplantation had begun. The initial evidence that blood transfusions affect recipient immunity beyond humoral alloimmunity came from clinical observations in patients receiving cadaveric renal allografts.[8,28] During the early history of renal transplantation, acute graft rejection during surgery was observed in alloimmunized recipients. This phenomenon was associated with prior transfusions, which, in the pre-erythropoietin era, were the only treatment for the anemia of renal failure. Some investigators were modestly successful at reducing alloimmunization in these patients through leukoreduction before transfusion. At that time, the sole available method of achieving leukoreduction was the use of washed or previously cryopreserved red cells, which were leukocyte reduced by about 80% to 90%, as well as plasma and platelet reduced. However, other investigators made a startling finding, which was received with substantial skepticism. They observed that transfused patients actually experienced overall improved renal allograft survival compared with nontransfused patients. This effect was later shown to be dependent on the transfusion dose and was not observed in those patients receiving leukocyte and plasma reduced blood transfusions (Fig. 52–1).[8,28]

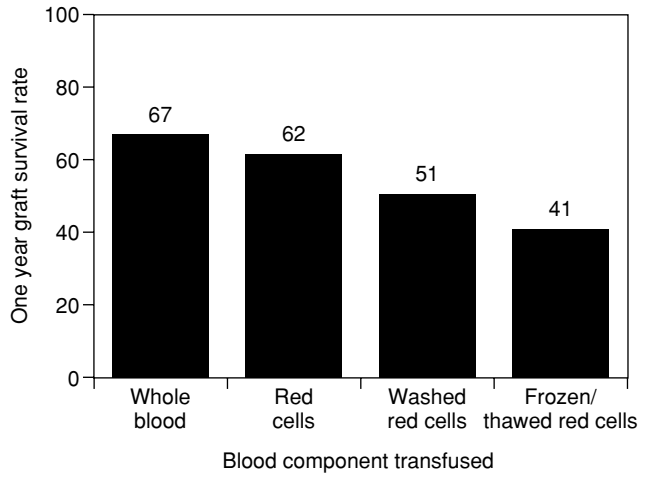

Figure 52–1 One-year kidney allograft survival in recipients of 1–5 units of allogeneic blood of the type listed is shown as a percentage of total patients with transplants. Transfusions with reduced content of allogeneic white cells, platelets, and stored supernatant plasma are associated with inferior 1-year graft-survival rates. (Data from the UCLA registry. Horimi T, Terasaki PI, Chia D, Sasaki N. Factors influencing the paradoxical effect of transfusions on kidney transplants. Transplantation 1983;35:320–323.)

Animal models supported the critical role of allogeneic white cells in mediating this "tolerogenic" result, whereas other studies[29] suggested that a similar effect could be mediated by platelet transfusions. This is of particular interest in light of recent findings that platelets and platelet-derived CD40L can stimulate secretion of prostaglandin E_2 (PGE_2) and other downregulators of cellular immunity.[30,31] Blood transfusions also appear to decrease rejection rates after heart[32] and liver[33] transplants. Donor-specific transfusions are remarkably effective at preventing rejection in animal models but are infrequently used for patients now that immunosuppressive drugs are highly effective at abrogating allograft rejection. A recent report found that the number of acute rejection episodes was inversely related to the number of blood transfusions in cardiac transplant recipients, most of whom received nonleukoreduced transfusions.[34]

TRANSFUSION AND AUTOIMMUNE DISEASES

Transfusion appears to affect favorably some autoimmune diseases thought to be mediated by cellular immunity. These include Crohn's disease (regional enteritis)[35] and rheumatoid arthritis.[36] In Crohn's disease, patients with larger sections of inflamed bowel and more-severe disease are more likely to be transfused during surgery for removal of diseased small bowel. Despite these higher risk factors for poor outcomes, transfused patients are actually less likely, or no more likely to have recurrences of their Crohn's disease than are nontransfused patients who have less-extensive and aggressive disease.[37] One potential explanation for these findings is a downregulation of the type 1 inflammatory process by allogeneic transfusion.

Similarly, rheumatoid arthritis is thought to be mediated in part by type 1 immunity and inflammation. In pilot studies, disease activity has been favorably influenced by transfusion of allogeneic white cells[38] or whole blood.[36]

TRANSFUSION AND REPETITIVE SPONTANEOUS ABORTION

One of the earliest observations regarding TRIM was that paternal or other unrelated blood transfusions improve the likelihood that women with repetitive spontaneous abortions will carry a pregnancy to term.[12] The clinical benefit is modest, and varied transfusion preparations yield different degrees of efficacy, but the effect is reproducible. This observation, although not of major clinical significance, is particularly intriguing, as successful pregnancy, similar to allogeneic TRIM, results in type 2 immune deviation, with increased expression of cytokines such as interleukin (IL)-4, IL-5, and IL-10.[39,40] Pregnancy is characterized by slightly increased risks from intracellular infectious organisms and tumors, presumably because of the mildly impaired type 1 immune defenses needed for optimal immune surveillance. One potential mechanism for the beneficial effects of transfusion in this setting is that allogeneic transfusions may downregulate pathologic type 1 immune responses that contribute to spontaneous abortion.[40]

Another parallel between the immunology of transfusion and pregnancy is the high frequency of alloimmunization and

humoral immune responses, precisely as would be expected in clinical settings in which type 2 immune deviation is present. Relevant to this hypothesis, red cell transfusions that are leukocyte reduced may be less likely to result in alloimmunization, not only to WBC antigens, but to red cell alloantigens as well.[26] Leukoreduced transfusions may provoke less type 2 immune deviation than do unmodified transfusions.

TRANSFUSION AND CANCER RECURRENCE

The allograft tolerizing effects of blood transfusion, by analogy with the drugs used to prevent rejection, was termed an *immunosuppressive* effect.[41] Could this effect, beneficial in organ transplant recipients and patients with autoimmune disease or repetitive spontaneous abortions, lead to unfavorable outcomes in clinical situations in which intact recipient cellular immunity is needed? Would patients undergoing surgery or those with cancer experience negative outcomes from "transfusion immunosuppression?"

In the late 1970s, a group from Newcastle, England, observed that animals with tumors had more rapid tumor growth if transfused with allogeneic as opposed to syngeneic blood.[42] The clinical analogy would be the use of allogeneic (homologous) versus autologous transfusions. In 1982, Burrows and Tartter[9] reported that patients in a colorectal cancer trial had earlier and more frequent recurrences of their cancers if they were transfused at the initial surgical resection. Similar observations were made for most other surgically treatable tumors, although about one third of the studies did not achieve statistical significance despite uniformly poorer outcomes in the transfused patients.[43,44]

One possible explanation for the association between allogeneic transfusion and earlier tumor recurrence is simply that the need for transfusion is confounded by size or aggressiveness of the tumor. Patients who require transfusions may do so because they tend to have larger, more aggressive, and difficult-to-resect tumors. This confounding certainly explains some of the association. However, a number of studies observed that even in patients closely matched for prognostic factors, transfused patients had more frequent or earlier cancer recurrences.[45,46] In addition, transfusion practice is quite variable in almost all clinical settings, due to a lack of accepted, uniform criteria for commencing transfusion therapy. Although transfusion therapy is not given randomly, neither is it given in consistent fashion driven by evidence-based transfusion triggers. Thus it would have been surprising if the two- to threefold difference seen in tumor recurrence is completely due to confounding. In epidemiologic investigations, two- to threefold differences in outcomes usually prove to be causal relations, at least to some extent.[47,48]

When these observations appeared in the 1980s, the hypothesis that the immune system was involved in cancer outcome was falling out of favor. Failures of immune-based therapies in patients, such as interferon and bacille Calmette-Guérin (BCG) vaccination, which had efficacy in animal models, were largely responsible.[49,50] Also, immune responses to human tumors were rarely demonstrable. The possibility that "successful" tumors can evade and/or repress host immune responses had not yet been proposed or proven.[51,52] Thus the initial observations of a relation between perioperative transfusion and cancer recurrence were met with intense skepticism, much as was the case for the initial studies of the allograft-enhancing effects of blood transfusions.

Nonetheless, several investigative findings suggest that the association between blood transfusion and cancer recurrence is causal. First, as in the renal transplant data, the type of transfusion affects the likelihood of recurrence. Whole blood transfusions are associated with greater cancer recurrence rates than are equivalent numbers of red cell transfusions (which are partially depleted of plasma, white cells, and platelets) (Figs. 52–2 and 52–3).[53–55]

Second, two animal models demonstrated that removal of allogeneic leukocytes reduced the number of lung metastases seen after transfusions.[13] Third, autologous transfusions reduced the recurrence rate in patients undergoing colorectal cancer resection, as compared with patients receiving allogeneic transfusions, in one randomized trial[56] but not in another.[57] The single study that examined leukocyte reduction of transfusions as a means of reducing adverse immunomodulatory effects showed no benefit,[58] and that was supported by results of another recent report.[59]

Regrettably, few trials of leukocyte reduction, washing, autologous transfusions, or bloodless medicine and surgery techniques have been published in oncologic surgery. These are extraordinarily challenging and expensive trials to perform because they require adherence to complex protocols, large numbers of patients, and, in particular, long-term follow-up. The one existing trial of washed, leukocyte-reduced transfusions in patients with cancer demonstrated a possible benefit in younger adults with acute leukemia.[60] However, this was a small pilot study, and clear-cut benefit was seen only in subgroup analysis, increasing the chances of selection bias and confounding.

Fortunately, a trend exists toward decreasing use of transfusions in cancer surgery,[17] largely due to the concerns about

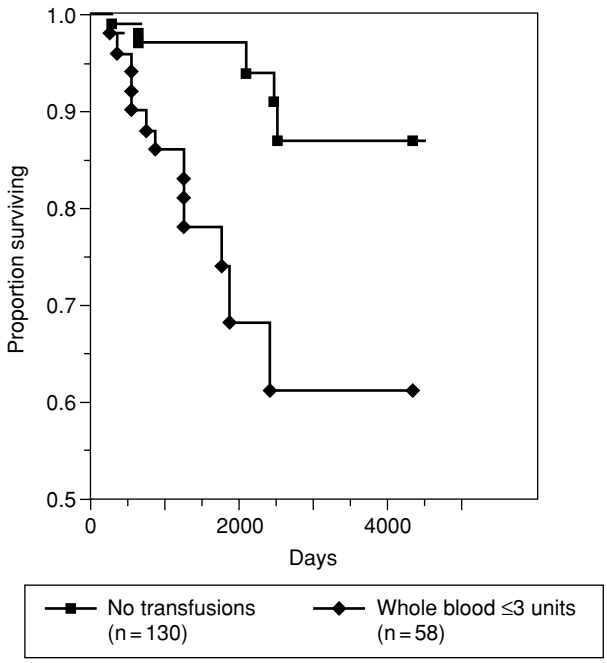

Figure 52–2 Kaplan-Meier plot of the proportion of patients remaining alive after initial surgical treatment for colorectal, cervical, or prostate cancer who received either no transfusions or ≤3 units of blood, at least one of which was whole blood. The two curves are statistically significantly different ($P < 0.001$), with the nontransfused patients having estimated mortality at 5 years of <15%, as compared with almost 40% in those receiving whole blood transfusions.[53,54]

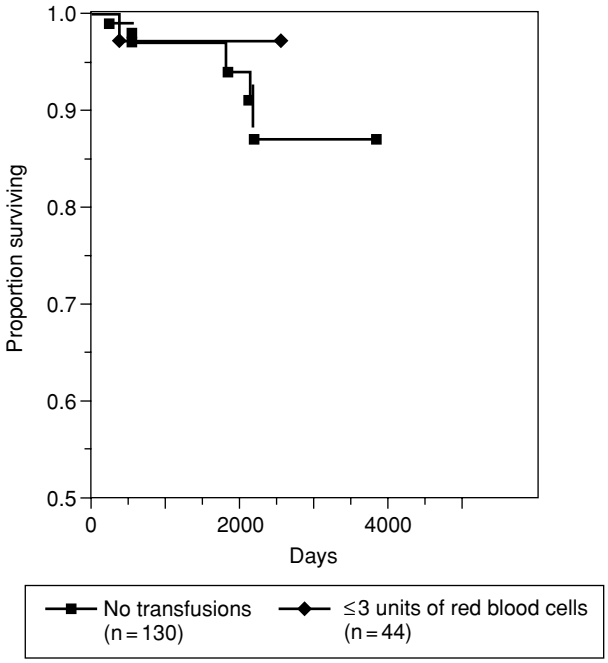

Figure 52–3 Kaplan-Meier plot of the proportion of patients remaining alive after initial surgical treatment for colorectal, cervical, or prostate cancer who received either no transfusions or ≤3 units of red cell concentrates. The two curves are not statistically significantly different.[53,54]

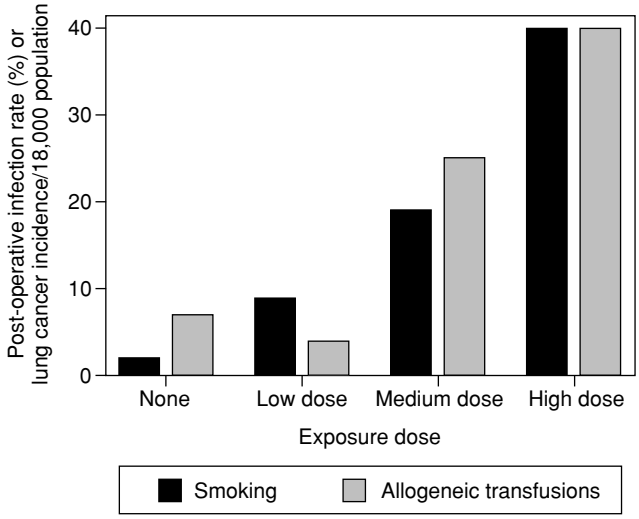

Figure 52–4 The relative risk of postoperative infection according to number of allogeneic transfusions[68,69] is compared with the relative risk of lung cancer according to number of cigarettes smoked.[154] The 5- to 10-fold increase in postoperative infections with increasing number of allogeneic transfusions, seen in many studies, which is in part abrogated by leukoreduced or autologous transfusions, provides prima facie evidence for a cause-and-effect relation according to Hill's principles of causation (including dose relation, size of the effect, underlying plausible mechanism, consistency across studies, and benefits of reducing the exposure).[47,48]

transfusion-transmitted human immunodeficiency virus (HIV) and hepatitis C. It is unknown whether this change in practice has contributed to decreases in recurrence rates in patients with surgically resectable tumors. With the implementation of universal leukoreduction of transfusions throughout much of the developed world, the possibility exists for before and after studies of cancer recurrence, but none has yet been published. When a 5- to 10-year follow-up period is available for patients treated after the introduction of universal leukoreduction, it may be possible to determine whether leukoreduced transfusions are less immunomodulatory in cancer surgery patients than unmodified transfusions. Our speculation is that both leukocyte reduced and washed transfusions may be needed to maximally benefit transfused cancer patients.

TRANSFUSION, POSTOPERATIVE INFECTION, AND MULTIORGAN FAILURE

Transfusions are associated with a dramatically increased risk of postoperative bacterial infection, as first reported by Paul Tartter[11,61] 20 years ago. Preoperative, intraoperative, or postoperative transfusion leads to a severalfold increase in the proportion of patients who develop an infection. This association has been confirmed in many other studies[62] and cannot be explained by confounding variables related to transfusion such as anemia, blood loss during surgery, duration of surgery, or hypotension. The quantitative strength of the association is striking. Patients who are transfused with more than 10 units of allogeneic blood experience a 5- to 10-fold increase in their likelihood of developing a postoperative infection.[63] This effect is observed in diverse surgical settings, and among studied causal relations is second in magnitude only to the association between smoking and lung cancer (Fig. 52–4). Thus the association between transfusions and postoperative infections is extremely unlikely to be explained by the bias and confounding that are limitations of most observational studies.[47,48]

It has been suggested that the effects of multiple confounding factors and a surrogacy role for transfusions might explain this association.[64] This hypothesis is quite improbable because of the extraordinarily variable and unsystematic way in which transfusion decisions are made.[65] A dose-dependent 5- to 10-fold increase in postoperative infections after allogeneic transfusion solely accounted for by confounding is extremely remote and would be unprecedented in clinical epidemiology.[47,48]

One limitation of published studies is that infection is often defined solely as culture-proven infections. This greatly underestimates the incidence of infectious morbidity, given the insensitivity of most culture techniques. This is particularly the case in surgical patients, who invariably receive prophylactic antibiotic therapy. It is preferable also to estimate infections by multiple surrogate measures including days of antibiotic treatment, length of hospital stay, and signs, laboratory tests, and symptoms of infection. Less comprehensive approaches are likely to underestimate infectious morbidity significantly. As discussed previously in this chapter, one additional body of evidence that contradicts the "transfusion as a surrogate marker for confounding variables" hypothesis is that perioperative transfusions are associated with better rather than worse clinical outcomes in patients receiving renal allografts[28] or in those with inflammatory bowel disease.[35] Were transfusion to be acting purely as a surrogate measure of clinically unfavorable comorbidities, these clinically favorable associations would not exist. To the contrary, as is discussed further, these altered outcomes support a common immunologic mechanism for both improved and poorer clinical outcomes in different clinical settings. Although some analyses that included many unrelated confounders did not find a significant association between transfusion and infection,[66] these types of

analyses are neither statistically nor scientifically sound.[67] Only confounders directly and causally linked to both transfusion and infection are appropriately included in statistical models. Introduction of multiple, causally unrelated, and irrelevant variables can lead to erroneous acceptance of the null hypothesis.

A number of animal models confirm that the association of allogeneic transfusion with postoperative infection is most likely cause and effect. Alexander and colleagues[14] demonstrated in mice that allogeneic white cells were more potent in mediating this effect than were red cells or plasma. Our group and many others observed that the association between transfusion and postoperative infection is not seen in patients receiving autologous blood, supporting an immunologic mechanism for the effect (Fig. 52–5).[68,69]

The best evidence for a causal relation between allogeneic transfusion and an increased risk of postoperative infection comes from randomized clinical trials of leukoreduced allogeneic transfusions versus unmodified blood transfusions, as well as studies of autologous versus allogeneic transfusions. These studies, discussed in detail further on in this chapter, demonstrate beyond a reasonable doubt that the incidence of postoperative infection, and probably that of multiorgan failure, in transfused surgical patients can be reduced by use of leukoreduced blood transfusions[15–18,58,70–73] or the use of autologous techniques.[19] In general, a 10% absolute reduction in postoperative infection incidence is possible by using leukoreduced transfusions compared with unmodified red cells. This means that for every 10 patients treated with leukoreduced transfusions, one less postoperative infection will occur as compared with patients treated with nonleukoreduced transfusions. Recent evidence from our own center suggests that leukoreduction of blood transfusions may also reduce the incidence of indwelling vascular-access catheter sepsis in a variety of nonsurgical settings by perhaps 30% to 40%.[74]

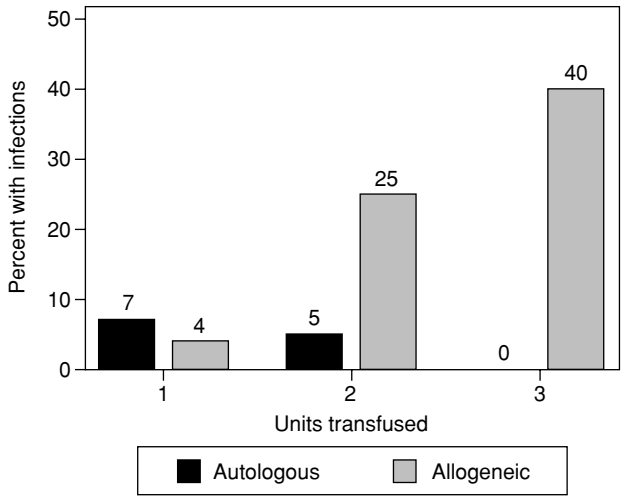

Figure 52–5 Patients undergoing posterior or anterior, cervical or lumbar spinal fusion, or primary hip replacement surgery, without malignancy, autoimmune diseases, or diabetes were grouped according to whether they had received only autologous blood or only allogeneic (homologous) blood. The proportion with culture-proven or clinically evident infections, grouped according to number of units of blood transfused, is shown. The differences between autologous and homologous recipients are statistically significant at doses of 2 or 3 units, but not for 1 unit of blood. This dose-response relation also was evident when days of antibiotics and length of hospital stay were measured. Infections were predominantly away from the wound site: two thirds were cellulitis, urinary tract, or pulmonary. Data are pooled from two studies.[68,69] (Reprinted from Anderson KE, Ness PM [eds]. Scientific Basis of Transfusion Medicine. Elsevier, 2000, p 437, with permission.)

The association between transfusion and postoperative infection is also reflected in observations of a dose-dependent increase in multiorgan failure in transfused surgical patients.[75–77] Multiorgan failure is often initiated by infection in seriously ill patients. This association is not explained by confounding factors and has been detected in randomized clinical trials as well. Multiorgan failure and death after cardiac surgery appears to be reduced in patients receiving leukoreduced transfusions.[18]

Platelet transfusions also have been associated with a five-fold increase in postoperative deaths after cardiac surgery, after adjustment for other risk factors.[78] Such a large effect is unlikely to be explained primarily by confounding.[47,48] The association between platelet transfusion and mortality may be partially abrogated in patients receiving postoperative aspirin.[79] Whether the association between platelet transfusion and mortality is mediated by a predisposition to infection due to immunomodulatory effects of transfusions,[18,80] a prothrombotic effect of storage activated platelets being transfused,[81–83] exacerbation of inflammatory responses from transfused platelet CD40L and sCD40L,[30] other bioactive molecules or cells, or other mechanisms, will require further investigation.

Wound healing may also be impaired after allogeneic transfusions.[84–86] Both randomized trials and before-and-after studies suggest that leukoreduction of transfusions may reduce the risk of postoperative multiorgan failure[18] and improve wound healing.[87] It is unknown whether storage time of transfused blood influences these complications, but this seems possible.[88–90] Recent evidence suggests that postoperative morbidity and death due to immunologic mechanisms may also be increased by transfusion of ABO-mismatched blood components containing incompatible antigen or antibody.[91–93]

TRANSFUSION AND ANTIVIRAL IMMUNITY

Given the association between transfusion and postoperative bacterial infection, it was hypothesized that allogeneic transfusions might also impair host resistance to viral infection. Epidemiologic evidence suggests that transfusion accelerates the appearance of clinical manifestations of HIV-1[94] and cytomegalovirus (CMV) infection.[95] However, in end-stage HIV-1 infection, a randomized trial of leukoreduced transfusions failed to identify any immunomodulatory effects that promote viral replication or shorten survival.[96] With regard to this last trial, it has become evident in TRIM studies that multicenter studies, which typically involve small numbers of patients at large numbers of hospitals, may be less able than single-center studies to detect improved outcomes because of substantial variations in clinical practices that influence infection or survival.

Viral infections play a role in lymphoma in both animal models and humans, and prior allogeneic transfusion has been associated with the development of non-Hodgkin's lymphoma, specifically the B-cell variants.[97] Not all studies have found this association. If the association is causal, it is unclear whether viral transmission or TRIM is primarily responsible, but either or both mechanisms could be involved. TRIM drives B-cell proliferation and maturation

through promotion of type 2 (Th2) immunity and downregulates type 1 (Th1) immune functions that are thought to be relevant in antiviral immunity and tumor surveillance (Fig. 52–6). Thus although the hypothesized potential of transfusion to impair host defenses to viral infection is plausible, in that transfusion downregulates natural killer cell and macrophage/monocyte cytocidal functions and promotes Th2 immune deviation, no definitive conclusions are possible, given the modest data at hand.

MECHANISMS OF TRANSFUSION IMMUNOMODULATION

Transfusion involves intravenous infusion of large doses of blood cells, proteins, lipids, and other blood constituents diluted with preservative anticoagulant solution, as well as the breakdown products that result from storage lesions. The only natural circumstances in which the immune system is exposed to such high doses of intravenous antigen are self-antigens and pregnancy.[40,98] The immune system has evolved to respond to these two situations with unresponsiveness or tolerance and to provide defense against dangerous foreign antigens that are non-self.[23] Pathogens are microorganisms, present in small quantities, at mucosal or skin locations, or altered self (i.e., cancer cells in small numbers), largely in organs. It stands to reason that large quantities of intravenous antigen containing both self and non-self determinants leads to unresponsiveness rather than allosensitization. In particular, this appears to be the case when the clinical setting is that of decreased host immune function (e.g., the immaturity of fetal life, surgical stress).

The classic investigations of Medawar and colleagues[27] proved that exposure to foreign antigens during fetal life can produce tolerance to skin grafts from the tissue donor. Felton[99] reported that when pneumococcal antigen was administered at high doses, animals have reduced capabilities for subsequent humoral immune responses to antigen administered by routes and in doses that otherwise cause sensitization ("immune paralysis"). In 1951, Snell and Kaliss[100] demonstrated that infusions of tissue extracts from allogeneic murine donors before tumor implantation led to accelerated tumor growth. Even serum transfusion before implantation led to the death of most of the mice from tumor progression. Saline-transfused control animals uniformly rejected the implanted tumor and survived. Interestingly, of all the tissue extracts transfused, infusions of lyophilized red cells were the only ones that failed to enhance tumor growth.

Whereas most studies have focused on the role of transfused allogeneic white cells and their secreted mediators or breakdown products,[101] clinical data suggest that stored supernatant plasma may also be immunomodulatory.[94] In addition, recent investigations confirm that platelets are a source of immunomodulatory mediators, such as vascular endothelial growth factor (VEGF), soluble CD40L, and transforming growth factor-β1 (TGF-β1).[30,31,102–105] In addition to platelet components, platelet-derived mediators such as soluble CD40L are also present at high concentrations in nonleukoreduced red cell concentrates and whole blood.

Allogeneic transfusions in animals result in diminished mixed lymphocyte culture reactivity, diminished antigen processing by macrophages, upregulation of both suppressor/regulatory cells and humoral immunosuppressive mediators, impaired cell killing, and production of anti-idiotypic antibodies that are immunomodulatory in vitro.[106,107] These findings indicate that impaired or dysregulated cellular immunity is likely a key mechanism underlying TRIM. Many investigations report that the presence or absence of allogeneic WBCs in the transfusion is critical to observing immunomodulatory effects, but plasma, red cells, and even purified, soluble class I

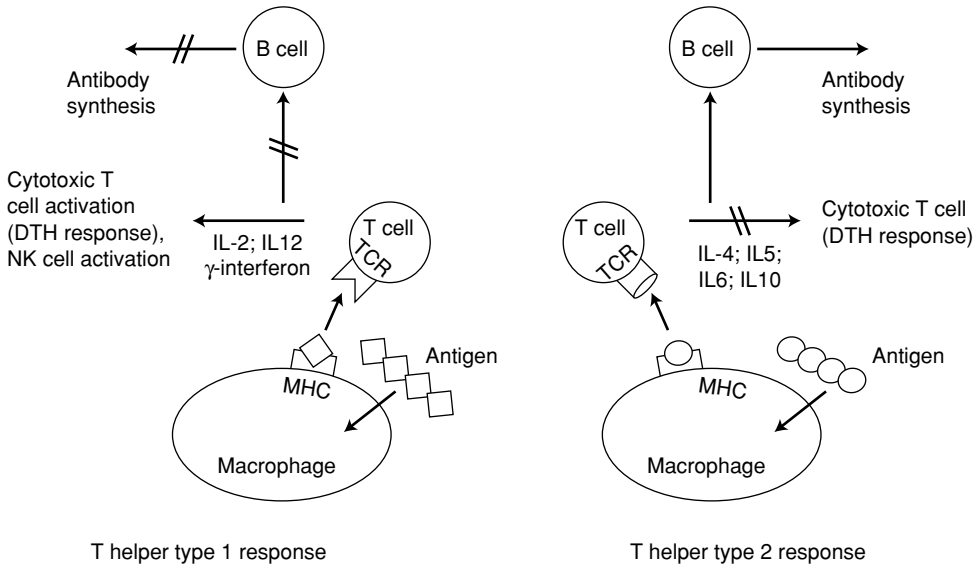

Figure 52–6 A schematic view of how alloantigens are processed by macrophages and presented to T cells is shown, with emphasis on the distinction between responses that primarily involve Th1(type 1) or Th2 (type 2) cytokines. Similarly, type 1 or type 2 deviated dendritic cells, macrophages, and CD8 cytotoxic lymphocytes have been identified. Allogeneic transfusions appear to promote primarily type 2 cytokine secretion patterns with reciprocal downregulation of type 1 cytokine secretion. Many cellular immune functions are downregulated by immune deviation, including cytotoxic T cell and NK functions.[98,155] DTH, delayed-type hypersensitivity; TCR, T-cell antigen receptor; MHC, major histocompatibility complex; NK, natural killer; IL, interleukin. Reprinted from Anderson KE, Ness PM [eds.]. Scientific Basis of Transfusion Medicine. Elsevier, 2000, p 429, with permission.)

histocompatibility antigens or peptide fragments of class I molecules[108,109] can have similar effects. The simultaneous presence of alloantigen and key mediators probably accounts for many of the clinically observed TRIM results, because autologous or syngeneic blood does not generally mediate these effects.

TRIM in the allotransplant setting is mediated at least in part by the effects of increased PGE_2 and decreased IL-2 production. Inhibition of PGE_2 secretion by indomethacin or anti-PGE_2 antibody abrogates the transfusion allograft enhancement effect.[110] In another animal model, administration of exogenous IL-2 reversed the blood-transfusion tolerance induction for renal allografts.[111] Allogeneic transfusions also impair the ability of murine and human mononuclear cells to secrete IL-2 in response to a variety of in vitro stimuli.[22,112] Table 52–1 lists some of the immunologic alterations that have been consistently described in transfused animals and patients.[98,106,107]

Several mechanisms appear to play a role common to many or even most of these clinical settings. One model for transfusion immunomodulation is depicted in Figure 52–6.[20–22,98,112–115] Immune deviation involving increased secretion of type 2 (Th2) cytokines (e.g., IL-10, IL-4) and decreased secretion of type 1 (Th1) cytokines (e.g., γ-interferon, IL-2) is one proposed mechanism by which transfusion immunomodulates recipient immune responses to allogeneic organs, tumors, and the fetus. Effective immune responses against tumors and organ allografts are thought to be primarily Th1 in nature,[116] as is rejection of the fetus as an allograft.[39] Although this scheme no doubt oversimplifies the intricate biology of such processes, clinical and animal studies demonstrate that allogeneic transfusions alter cellular immunity by promoting immune responses with increased production of IL-10, IL-4, and TGF-β. These mediators downregulate natural killer (NK) and T-effector cell functions, as well as phagocytic cell functions and generally function as anti-inflammatory mediators. NK and T cells are critical to maintaining antitumor, anti-allograft, and antimicrobial immunity. Thus, their dysregulation after allogeneic transfusion provides one plausible unifying mechanism to explain a variety of seemingly unrelated clinical outcomes.

To complicate the clinical picture, surgery alone, absent transfusion, causes immune deviation toward type 2 cytokine secretion. This effect likely accounts in part for the reduction in delayed-type hypersensitivity responses seen for the first week or two after surgery.[117–119] Whether this altered immunity is due to surgical trauma, anesthesia, or other drugs is not entirely understood. These immune effects are additive with the effects of transfusion in the clinical setting, and impairments of cellular immunity can last for days to weeks. From both immunologic and clinical standpoints, it is of interest that immune dysregulation is not seen or is seen to a lesser degree in patients receiving only autologous blood,[115,118,120] or leukocyte-depleted transfusions.[15,16,121]

Finally, evidence indicates that infusion of apoptotic allogeneic WBCs facilitates type 2 immune deviation,[122] organ allograft acceptance,[123,124] and multiorgan failure[122] in experimental animals. Apoptotic WBCs and platelets, as well as red cells, accumulate during blood storage and are selectively removed by leukocyte-reduction filters.[125] Thus, infusion of storage-damaged apoptotic allogeneic cells may provide one mechanism by which T cell, macrophage, and dendritic cell immunity is biased toward type 2 cytokine secretion, and explain why leukocyte reduction reduces adverse immunologic and clinical effects.[126]

Immune deviation, greater in intensity but similar in principle to that seen in pregnancy, is not the only event that occurs with allogeneic transfusion. However, it is the only current hypothesis that could account for a broad range of seemingly contradictory clinical findings that range from reduced spontaneous abortion, allograft rejection, and autoimmune disease, to increased postoperative infection and cancer recurrence (Table 52–2). In summary, TRIM is a pleiotropic phenomenon. It is extremely unlikely that any single mechanism fully accounts for the effects of transfusion on organ transplants, postoperative infection, cancer recurrence, pregnancy, and autoimmune diseases.

Table 52–1 Allogeneic Transfusion Effects on Immune Function

1. Decreased Th1 and increased Th2 cytokine production in vitro
2. Reduced responses in mixed lymphocyte culture
3. Decreased proliferative response to mitogens or soluble antigens in vitro; impaired delayed-type hypersensitivity skin responses
4. Increased CD8 T-cell number or suppressor function in vitro
5. Decreased natural killer cell number and activity in vitro
6. Decreased CD4 helper T cells number
7. Decreased monocyte/macrophage function in vitro and in vivo
8. Enhanced production of anti-idiotypic antibodies suppressive of mixed lymphocyte response in vitro
9. Decreased cell-mediated cytotoxicity (LAK) against target cells in vitro
10. Humoral alloimmunization to cell-associated and soluble antigens

METHODS TO MITIGATE TRANSFUSION IMMUNOMODULATION AND REDUCE MORBIDITY AND MORTALITY

Reducing the damaging effects of transfusion immunomodulation is not straightforward, as the underlying mechanisms have not been entirely elucidated. For example, it is not certain whether transfused cells and molecules other than allogeneic WBCs cause significant changes in clinical outcomes. However, this seems probable. Supernatants from

stored platelet concentrates contain significant amounts of immunomodulatory mediators such as TGF-β1 and sCD40L, which are potential causes for some observed associations. Platelets express surface CD40L, which has been linked in preliminary work to acute lung injury.[83,127] Storage-damaged apoptotic red cells express phosphatidyl serine, which could interact with receptors on endothelial or other immunocompetent cells. Transfusion components stored under variable conditions for various periods may have differing immunomodulatory effects. Clinical data suggest that transfused whole blood has more potent immunomodulatory effects than do red cell concentrates. Whether this is attributable to variations in platelet or WBC content, supernatant plasma, or other variables is not known. Differences in leukocyte-reduction methods may yield sufficiently varied numbers of residual platelets in the transfused component that this accounts for some of the inconsistency of the results reported in randomized trials.

Despite these caveats and uncertainties, three well-established methods are known for mitigating the immunomodulatory complications of transfusion. The first is entirely avoiding transfusion via bloodless medicine and surgery practices.[128] The second is avoiding or reducing allogeneic transfusions by use of autologous transfusion, hemodilution, and blood salvage.[19] The third is administering only leukoreduced (also platelet-reduced) red cell transfusions by using high-efficiency WBC adherence filters.[15–18,58,70–73,129]

Two randomized trials of autologous predeposit versus allogeneic transfusions have produced opposite results. Heiss and colleagues[56,118] reported reduced infections and cancer recurrences in patients receiving autologous transfusions, whereas Busch and colleagues[57] found no benefit. Both these studies are limited by the most significant problem in studies of autologous or leukoreduced transfusions, which is a high protocol-violation rate. A high percentage of patients in these studies received no transfusions or the wrong types of transfusions because of insufficient availability of autologous or leukoreduced blood. When patients with protocol violations were removed from the database, the benefits of reduced cancer recurrence were much clearer in the study of Heiss and colleagues. Another caveat for both of these studies is that the control arms were buffy coat depleted (60% to 80% leukoreduced) allogeneic red cells. This partial leukoreduction of the control transfusions minimizes the opportunity for detecting a benefit because allogeneic WBCs/platelets are important mediators of TRIM.

In addition, a potentially important difference may be that the Heiss study[56,118] was a single-center study, whereas the Busch study included multiple centers.[57] Most single-center trials of leukocyte depletion or autologous transfusion have demonstrated reductions in morbidity or mortality compared with unmodified allogeneic transfusion recipients. Most multicenter trials have failed to find such benefits. The variability introduced by small numbers of patients treated by many diverse clinical protocols may have obscured potential benefits. Such variations from center to center have been shown to account for the variability in postoperative infection rates in Israeli medical centers.[130] It is interesting that an initial multicenter study by investigators in Leiden failed to find a benefit to leukoreduced transfusions in colorectal cancer surgery,[58] but a subsequent single-center study from the same investigators found beneficial effects of leukoreduced transfusions on morbidity and mortality after cardiac surgery.[18] Variation in infection-control and surgical techniques, such as time of administration of prophylactic antibiotics, significantly affects infection rates, and these uncontrolled variables may confound studies of transfusion interventions.

One large randomized trial found that leukoreduced transfusions benefited neither mortality, morbidity, length of stay, nor hospital costs.[131] These data did support the probability that leukocyte reduction was cost neutral. This study had a number of limitations. Many patients were included who might not be seriously affected by TRIM. Outpatients with anemia of chronic disease, medical inpatients with modest blood loss or hypoproliferative anemias, and other subgroups may affect the power of a large study to detect a benefit in those who are more seriously at risk, such as surgical and critical care patients. Second, as in other studies with high protocol-violation rates, more than one in eight patients in the leukoreduced arm of this study actually received nonleukoreduced blood. Third, the proportion of patients with protocol violations was significantly greater in the leukoreduced arm of the study than in the control arm. A likely explanation for this failure of randomization is that when supplies of leukoreduced blood ran short, technical staff switched patients to the nonleukoreduced protocol. As TRIM is dose dependent, this effectively removed from the leukoreduced arm of the study the heavily transfused patients most likely to benefit. This study thus cannot definitively address whether leukoreduction reduces morbidity and mortality in surgical and critical care patients, which are the settings in which the largest clinical and cost benefits may be observed.[132]

Over the last decade, a number of "meta-analyses" of randomized trials of leukoreduced transfusions to reduce postoperative infections have been published, claiming to demonstrate that leukoreduction is of little or no benefit in reducing postoperative infection.[66,133–139] However, these studies have methodologic problems. One error is failing to calculate a summary odds ratio for the effects of leukoreduced transfusions. Without a summary odds ratio, the single number representing the cumulative results of the published clinical trials, no meta-analysis is produced, but only a review containing the authors' opinions. The rationale for not calculating a summary estimate was the presence of statistically significant heterogeneity in the published original studies. Statistical heterogeneity is not a valid scientific rationale for failing to calculate a summary odds ratio, but rather is an indication for use of a random effects meta-analysis, and for further exploration of the data to investigate the sources of heterogeneity.[140]

Even more scientifically questionable is that these analyses include many nontransfused patients. Nontransfused patients compose as many as three fourths of the patients in some clinical trials in the published graphs. Nontransfused patients cannot provide answers to the question of whether TRIM has clinically significant effects, nor whether leukoreduction can reduce such effects. Most seriously, some meta-analyses do not represent the actual data from the original studies. For some of the clinical trials, the meta-analyses used data that represent "imputed" outcomes created by the authors of the review.[66,133–139]

The original authors of the studies analyzed only the patients who actually received transfusions because these are the only relevant patients for assessing whether leukoreduction has any benefits. Retrospectively to create an "intention to treat" analysis including the nontransfused patients, the

meta-analysts divided in half the number of nontransfused patients and infections reported in these nontransfused patients. They then added these infections and nontransfused patients back to the actual reported data on transfused patients, as originally published. It is a violation of the scientific method to include nontransfused patients in a study of leukoreduced transfusion outcomes, whether using actual or fictional data. Estimates from properly performed meta-analyses that restrict the analysis to actual data from about 3000 patients who were transfused in eight randomized trials recently demonstrated beyond reasonable doubt that leukoreduction decreases the odds of postoperative infections in transfused surgical patients by about 40% to 50% compared with unmodified red cells, whole blood, or buffy coat–poor red cells.[129,141] This corresponds to an absolute risk reduction of 10%, yielding a number to treat of 10. For every 10 surgical patients receiving leukoreduced, instead of unmodified, transfusions, one patient will be protected from developing a postoperative infection that otherwise would have occurred (Fig. 52–7). This figure probably understates the benefits of leukoreduced transfusions because protocol violation rates of up to 11% occurred in the leukoreduced arm of these studies.

A number of implementation trials of universal leukoreduction have been reported.[142–148] These have yielded variable results, perhaps not surprisingly, when derived from before-and-after studies of infection incidence, length of stay, and other variables heavily influenced by possible temporal changes in case mix, other clinical interventions, and the confounding effects of multi-institutional observational studies. Five of the seven studies reported reductions in mortality, morbidity, and/or costs,[144–148] and three of the studies reported patient cohorts with no apparent clinical benefit.[142,143,146] None has demonstrated significant increases in morbidity, mortality, or costs with institution of universal leukoreduction, suggesting that, at worst, leukoreduction is cost neutral and causes no harm, whereas at best it can reduce morbidity, mortality, and costs significantly.

These benefits of leukoreduced transfusions are not minor public health concerns.[74,149] Depending on the percentage of the epidemiologic association that is causal, the number of TRIM–associated deaths could be as many as tens of thousands per year, far exceeding those due to other transfusion complications.[132] The opportunity to improve care involves not only morbidity and mortality averted, but also significant cost savings. Investigators in Rochester, New York, and Aarhus, Denmark, have estimated these savings at $1000 to $2000 per leukoreduced or autologous unit transfused instead of an allogeneic unit.[144,150,151] By extrapolating from these data, the estimated savings to the United States health system from universal leukocyte reduction of allogeneic transfusions to surgical patients could be as much as $6 to $12 billion per year, or 1% to 2% of the national health budget at that time.[152]

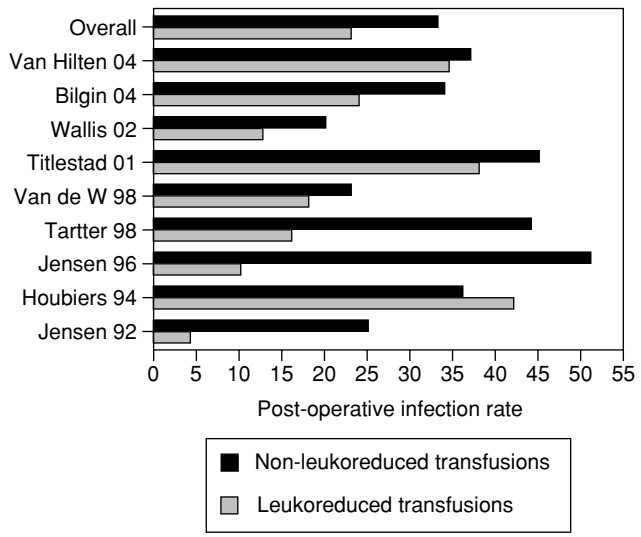

Figure 52–7 The postoperative infection rates observed in nine randomized trials of leukoreduced versus unmodified transfusions in colorectal or cardiac surgery are shown according to randomization arm (intention to treat). Six of the nine studies found statistically significant reductions in postoperative infections with leukoreduced transfusions, and in eight of nine studies, the infection rate was lower in the leukoreduced arm of the study. Nontransfused patients are excluded from these data, but patients with protocol violations (range, 0–11%) remain in the arm to which they were originally randomized. Overall, the infection rate in 1637 patients randomized to receive leukoreduced transfusions was 23%, as compared with 33% in the 1456 patients randomized to receive whole-blood, buffy-coat-poor, or unmodified red cell concentrates (equivalent to a 36% decrease in relative risk with leukoreduced transfusions; $P = .005$ in a random-effects model meta-analysis performed by Drs. Gary Lyman, Hongkun Wang, and Hongwei Zhao of the University of Rochester; unpublished data).

SUMMARY

Transfusions of allogeneic blood to animals or patients are immunomodulatory. Transfusions alter cellular adaptive immunity, innate immunity, and lead to both favorable and unfavorable reduced or increased inflammatory responses, depending on the clinical setting. Transfused patients are more likely to accept renal allografts. Whole-blood recipients have better allograft survival but higher colorectal cancer recurrence rates than patients receiving red cells alone. Allogeneic transfusion recipients are more likely to develop postoperative infections than are recipients of identical amounts of autologous transfusion. Recipients of leukocyte-reduced transfusions are less likely to develop postoperative infections than are recipients of unmodified red cells.

These observations are compatible with the finding that allogeneic transfusions lead to decreased type 1 and increased type 2 cytokine secretion in animal models and medical and surgical patients. Thus, immune deviation provides an initial concept in formulating a unifying theory of transfusion immunology, which can account for such diverse outcomes as the formation of alloantibodies (primarily a type 2 response), allergic reactions (also type 2 in origin), and downregulation of cellular immunity (a type 1 process).

The single explanation that best fits these varied clinical and laboratory observations is that allogeneic transfusions mediate clinically significant immunomodulation by modifying existing normal or abnormal immune responses.

Chapter 53

Post-Transfusion Engraftment Syndromes: Microchimerism and TA-GVHD

William Reed • Eberhard W. Fiebig • Tzong-Hae Lee • Michael P. Busch

INTRODUCTION

Microchimerism (MC), defined as the stable presence of a minority of non-self cells in a host, and graft-versus-host disease (GVHD), a disorder marked by attack and destruction of recipient cells by engrafted donor immune cells, may be viewed as related conditions that differ dramatically in clinical significance. MC is an expected outcome after transplantation, may be observed under certain conditions after transfusion,[1–8] and is regularly present during pregnancy as a result of bidirectional trafficking of viable cells between fetus and mother.[9,10] Microchimerism has been viewed by some as a welcome sign of stable graft acceptance in solid organ transplant recipients and during pregnancy[11,12] and consequently has attracted attention as a model for investigating immune mechanisms of tolerance.[13,14] Maternal MC also offers an exciting new venue for fetal diagnosis.[15–18] In and of itself, MC after blood transfusion is not a threat to recipients, although no detailed clinical evaluation has yet been conducted of patients with transfusion-associated (TA)-MC. Given that approximately 10% of patients transfused for severe traumatic injury develop long-term TA-MC,[19–21] this is an important area for future research. GVHD, conversely, is a common complication in transplant patients[22–24] and poses a rare but very serious threat to transfusion recipients.[25,26]

In this chapter, we review the discovery and current status of our understanding of MC, with a focus on recent findings related to TA-MC. We also provide a concise review of transfusion-associated GVHD (TA-GVHD). The disease process and clinical presentation of TA-GVHD is also covered briefly to highlight the similarities and differences with TA-GVHD. A number of recent reviews specifically address basic science and clinical issues of GVHD in the transplant setting in greater detail for the interested reader.[24,27,28]

MICROCHIMERISM

A chimera is a creature that harbors cells or tissues derived from another individual. In Greek mythology, the chimera was a beast with a lion's head and foreparts, a goat's body, and a serpent's tail. Medical research on chimerism can be traced to Ray Owen, who was born on a Wisconsin dairy farm in 1915. After studying agriculture and animal husbandry at the University of Wisconsin, he joined the faculty in the Department of Genetics and turned his attention to the study of bovine blood groups. Owen was fascinated by Lillie's observations,[29] published in 1916, that "demonstrated union of the circulatory systems between twin bovine embryos of the opposite sex." Lillie had shown that hormones from a male fetus could enter the circulation of its female twin, producing developmental abnormalities of the reproductive system in the female twin. This "modified" female twin is called a *freemartin* and is an early example illustrating the effect of hormones on sexual development.

Owen examined 80 pairs of bovine twins for patterns of twinning, placental vascular anastomosis, and blood-group antigens.[30] Finding that the majority of twin pairs displayed identical blood-group patterns, Owen reasoned that neither chance nor monozygotic twinning could explain the blood-group concordance. Rather, the exchange of erythroid progenitor cells through the same vascular anastomoses that carried Lillie's hormones was likely to be responsible. This remarkable insight, attributable more to Owen's powers of observation than to available technology, changed biology[31] and introduced the notion of blood cell chimerism that was recognized by Dunsford and colleagues[32] in their early description of a human blood-group chimera.

At the tissue level, chimerism can occur with solid-organ transplantation or, in the research setting, when a portion of an animal embryo is grafted to another species during the early stages of development. This method has been used extensively to investigate the developmental biology of the nervous system.[33] In humans, organ transplant recipients are tissue chimeras and, because lymphoid tissue often accompanies a solid-organ graft, passenger leukocytes may be "co-transplanted" and go on to establish their lineage within the recipient.[11] If the tissue of interest is blood, chimerism of its cellular elements, hematopoietic chimerism, occurs readily when stem cells are transplanted. Hematopoietic chimerism is said to be complete when essentially all of the recipient's hematopoietic cells are replaced with cells derived from the donor; chimerism is said to be partial (or mixed) when a substantial proportion of donor cells is present along with those of the recipient. MC is said to exist when only a small proportion (<2.5%) of hematopoietic cells within a recipient are derived from the donor, although these terms are often used imprecisely in the literature.

MC has been demonstrated during pregnancy and is expected after stem cell transplantation. More recently, stable MC has also been demonstrated years after both blood transfusion and normal pregnancy. In each of these settings, MC

has become established in the absence of any overt manipulation of host immunity. Because of these observations, which we explore in detail, a new conceptual relation is beginning to emerge to describe the relation between transfusion and transplantation, where transfusion is construed broadly to mean exposure to the viable mononuclear cells of another individual. This relation acknowledges a potential overlap between transfusion and transplantation. Despite this progress, no large scale formal study has used uniform sample collection and analytic methods of the prevalence and magnitude of MC in healthy populations as a function of specific allogeneic exposures. Table 53–1 illustrates this point by presenting a range of highly variable results for measured MC in various nonexposed populations. These types of data will be a critical base from which to advance our understanding of MC in the future.

Neither the conditions that permit stable MC in the setting of transfusion nor the biologic consequences of MC are yet understood. In some cases, MC appears to be an incidental finding in otherwise healthy individuals. In other cases, MC has been found in association with significant disease processes, including GVHD and adult-onset systemic sclerosis. In still other circumstances, chimerism may be a deliberate therapeutic strategy in transplantation or adoptive immunotherapy. Taken together, these data suggest a complex relation among allogeneic exposures, host immune factors, the development of MC, and the potential consequences of MC, either pathologic or therapeutic. We review methods for detection of blood cell MC before going on to discuss clinical studies that describe the presence of MC in various circumstances of health and disease, including blood transfusion.

Microchimerism Detection Methods

Karyotype, Microscopy, and Transfer Factor

Early studies of MC used karyotype analysis to identify allogeneic material.[5] This technique is convincing when it yields a positive result but is relatively insensitive and depends on laborious analysis of numerous individual cells and on male-female differences. The morphologic state of lymphocytes and the rate at which they take up thymidine have also been used to study transfusion-associated MC.[8] These important early studies by Schechter[4] first showed that transfused leukocytes caused lymphocyte activation in the recipient, and subsequent studies provided evidence that donor cells actually participate in the proliferative response. In 1969, Mohr and colleagues[34] reported on six patients who were shown to lack tuberculin sensitivity but received transfusions from donors with known sensitivity. When these investigators showed that each recipient transiently acquired the donor's tuberculin sensitivity after transfusion, great interest developed in "transfer factor." Transfer factor proved elusive to isolate or characterize but was suspected to be passenger leukocytes. Despite attempts to pursue these intriguing observations, detailed investigation would have to await the development of sensitive molecular methods, most often the polymerase chain reaction (PCR).

Polymerase Chain Reaction and Other Nucleic Acid–Based Detection Methods

Although PCR has extraordinary sensitivity derived from its ability to amplify a specific genetic sequence exponentially, the detection of a minor population of nucleic acid species against a highly similar genetic background present in vast excess is a technical problem for MC studies and requires unique PCR strategies to solve it. Several aspects of PCR methodology influence the detection of minor leukocyte populations. These features, summarized and annotated in Table 53–2, include the total input amount of nucleic acid in the assay, the degree and character of sequence differences distinguishing the minor and major nucleic acid population, whether the PCR strategy involves recognition of this sequence difference at the primer level or through probe specificity, preparation of isolated leukocytes or total DNA for analysis, whether quantitation is attempted, what methods are used for detection of amplified products, and finally, whether the reaction products are observed at each cycle (real-time or kinetic PCR) or only after the reaction is complete (end-point PCR).

We and others[35,36] have noted the possibility that primers that do not recognize the minor population as unique may be consumed early in the reaction through amplification of closely related sequences in the major population, which vastly outnumber the minor population sought; this would be expected to produce a false-negative MC assay. Thus, in our experience, the use of allele-specific primer pairs that recognize at least a two- to three-base-pair difference in the minor population is a superior approach and can usually be optimized for MC detection at levels as low as one chimeric cell per million host cells. Alternatively, a single-nucleotide polymorphism (SNP) can be used as an allogeneic target for detection of MC by PCR, but the detection sensitivity is reduced. Amplification strategies with less primer specificity

Table 53–1 Comparison of Reported MC Prevalence among Unexposed Healthy Populations

Lambert NC, et al[152]	Y-chr study of 26F SSC and 23 healthy never pregnant	15% of SSC+ MC+ 13% of healthy, never-pregnant women MC+
Yan Z, et al[153]	Quant Y-chr study of MC in healthy women and women with RA "without" sons	71 rheumatoid arthritis: 18% Y-chr pos 49 healthy: 24% y-chr pos Never pregnant, *n* = 48, 10% MC+ Daughters only, *n* = 26, 8% MC+ Spontaneous abortion, *n* = 23, 22% MC+ Induced abortion, *n* = 23, 57% MC+

Lee T-H, et al[84] Lee T-H, et al[3] Lee TH, et al[19]	Pretransfusion samples from 3 studies involving approximately 29 trauma and orthopedic patients. Both Y-chromosome and HLA methods	6 orthopedic: all negative (1995) 10 trauma non-LR: all negative (1999) 13 LR trauma: all negative (2005)

Table 53–2 **Polymerase Chain Reaction Strategies and Assay Characteristics Influencing the Detection of Minor Leukocyte Populations (Microchimerism)**

Characteristic	Options for Assay Development		
Degree of genetic difference between major and minor populations	Single-nucleotide polymorphism	Two- to four-base-pair difference	Wholly unique allogeneic sequence (e.g., X vs Y chromosome)
Primer specificity	Allele specific	Group specific	Locus specific
Observation of reaction	End reaction	End reaction labeled probe	Continuous by kinetic PCR (with or without specific hybridization probe)
Detection of amplified product	Sizing gel	Hybridization of amplified product using specific probe	DNA melting probe
Quantitation	None	Autoradiography standard dilutions	Cycle number by kinetic method

for the minor population are likely to be much less sensitive to the presence of MC because of nonspecific amplification of related host sequences. This principle is illustrated with the analysis of ex vivo cell mixtures in Table 53–3.[36]

Real-time PCR is a powerful strategy in which the accumulation of amplified product is observed at each amplification cycle rather than at the reaction's termination. This is accomplished by fluorometric quantitation of amplified product at the completion of each cycle. The detection chemistry may include direct intercalation of dyes such as ethidium bromide or SyBr green into accumulating double-stranded amplicons. Alternatively, TaqMan[37] or molecular beacon probes[38] can be used in detection. The advantages of real-time PCR techniques include ready quantitation of target sequence, because the copy number in the target analyte is directly related to the cycle number at which the reaction becomes positive. Real-time PCR assays based on dye intercalation, when properly validated, can achieve sensitivity and specificity the same as or better than labeled probe-based systems, at much lower cost.[39–41] However, probe-based systems offer the advantage of simultaneous detection of multiple target sequences, including internal control host sequences, if multiplexed PCR assays are optimized. Potential disadvantages of real-time PCR include the need for relatively expensive equipment and proprietary reagents. Furthermore, if probe hybridization is not used, the reaction product's precise identity may be less certain, although this can be addressed through proper assay validation, analysis of melting curves to confirm size of amplicons, and sequencing of reaction products where needed. Nested PCR methods have also been applied in analyses of MC.[42,43] Although the possibility for amplicon contamination with this method has led some groups to avoid it, nested PCR may provide some absolute advantage in sensitivity. Recent development of PCR assays based on insertion-deletion (InDel) polymorphisms[44] has provided an excellent new tool for chimerism analysis, both in the post-transplant setting and in the analysis of low-level chimerism in the research setting.[44a]

Nonamplification nucleic acid–detection methods such as fluorescence in situ hybridization (FISH) have also been applied to the detection of MC. The limited range of sensitivity of FISH derives from the need to analyze individual cells laboriously, making this method more suitable for detection of higher-level MC, such as in the post-transplantation setting. FISH has been valuable as an independent method to confirm MC demonstrated by PCR, and to study pathogenetic mechanisms by characterizing phenotypes of MC cells and interactions between donor and host cells in tissues. Microsatellite markers and analysis of variable-number tandem repeats (VNTRs) have also been widely used in chimerism analyses, but, like FISH, are generally suited to analysis of higher-level (mixed) chimerism encountered in the stem cell transplantation setting.[45]

Table 53–3 **Proportion of Chimeric Cell Populations Detected in Ex Vivo Cell Mixtures as a Function of Amplification Strategy**

	Percentage Allogeneic (Chimeric) Cell Composition			
Amplification strategy	10%	1%	0.1%	0.01%
Locus specific	17/18	0/16	0/18	1/17
Group specific	21/21	21/21	21/21	16/21
Allele specific	12/12	21/21	21/21	21/21

Rare Event Analysis and Stochastic Detection

When the minor leukocyte population sought is present only at extremely low levels, detection of MC may become stochastic; that is, allogeneic material may or may not be present in the limited sample volume processed for analysis in a single PCR reaction. Attempts to amplify much more than 10 μg of DNA in a single reaction predictably lead to PCR inhibition. To approach this problem of stochastic detection, larger volumes of blood must be analyzed in multiple parallel aliquots under identical reaction conditions. Such enhanced input assay methods are probably necessary to give meaning to a negative result in the study of rare events,[46] such as very low level MC.

Clinical Studies of Microchimerism

Microchimerism in Hematopoietic Stem Cell Products

Hematopoietic stem cell (HSC) products include bone marrow, cord blood, and mobilized peripheral blood. It has long been known that an increased risk for GVHD exists when the donor is a parous woman. As cord blood began to be used for clinical transplant, concern was raised that

maternal cells in the product could include immunocompetent T lymphocytes that might increase the risk for GVHD in recipients. Although studies have documented maternal cells in cord blood–derived stem cell products,[47–50] these MC cells do not seem to play an important role in GVHD after cord blood transplantation. Recently, Adams[51] reported that in a study of 29 growth factor–mobilized peripheral blood mononuclear cell (G-PBMC) products from female donors, 34% were positive for male DNA, including $CD34^+$-enriched fractions, presumably derived from male fetuses during previous pregnancies. Although more study is needed, the authors suggested that these chimeric cells may contribute to the incidence of GVHD after transplant with marrow or mobilized peripheral blood from parous female donors.

Bidirectional Microchimerism at the Maternal-Fetal Interface

During pregnancy, exchange of blood across the placenta occurs in both directions. We review several key clinical studies of MC at the maternal-fetal interface.

Lo and associates[10] were the first to document the bidirectional nature of this phenomenon in an analysis of 66 mother-child pairs studied at the time of parturition. The investigators used PCR assays targeting several common polymorphisms, including Y chromosome, β-globin variants, and glutathione S-transferase genotypes. They found fetal cells in the maternal peripheral blood in 26 of 51 informative cases. Maternal cells were detectable in the corresponding placental blood in 16 of 38 informative cases. The authors found no obvious pattern to the directionality of cell trafficking, although relatively few of the cases were informative in both directions, and the genetic markers used did not include human leukocyte antigen (HLA) alleles, so maternal-fetal histocompatibility, a factor thought by some to be potentially important in determining cell persistence, could not be examined.

Bianchi and colleagues[9] studied 32 pregnant women and 8 nonpregnant control women who had given birth to a male fetus 6 months to 27 years earlier. Flow sorting was applied to these samples to isolate leukocyte subpopulations, including a stem-cell progenitor fraction; these were then analyzed for Y chromosome–specific sequences by using nested and nonnested PCR techniques. Thirteen of 19 currently pregnant women were positive for male DNA in the sorted CD34+ fraction, whereas 4 of 13 nonpregnant women were also positive. Because the latter women had a history of either male pregnancy or termination of pregnancy of unknown gender, the positive results were interpreted to indicate that male cells can persist as long as 27 years postpartum in some pregnant females. This study, although quite convincing overall, suffered from the absence of control samples from prepubertal females.

Lo and coworkers[52–54] in Hong Kong have extensively studied the presence of fetal DNA in maternal plasma and serum. Studying 43 pregnant women who delivered male infants, they found Y chromosome–specific DNA in 24 (80%) of 30 maternal plasma samples and in 21 (70%) of 30 serum samples, whereas no positive results occurred among nonpregnant control women or among women carrying female fetuses. These and other findings led Lo's group to approach the clinical problem of determining the Rh D genotype of a fetus carried by an Rh-negative mother through analysis of circulating DNA in the maternal plasma.[55] Among 42 women in the second or third trimester, they obtained perfect concordance for Rh type compared with serologic postnatal Rh typing. Among the 15 first-trimester women, Rh typing was concordant in 13, with two Rh-positive fetuses yielding false-negative PCR results. A recent clinical study by Brojer and others.[56,57] involving 255 Rh D–negative pregnant women found that 90% of samples were suitable for analysis (based on presence of fetal DNA by using a non–Rh D marker) and that prenatal typing had a 99.6% predictive value. Quantitative study by our group of the time course of fetal DNA in the maternal circulation during pregnancy demonstrated that much more fetal DNA exists in the plasma than in the leukocyte compartment, and that copy number increases to its highest levels during the third trimester before decreasing precipitately at parturition.[58] Whether this plasma DNA is derived from trophoblasts, fetal leukocytes, or parenchymal tissues is not known.

Because plasma DNA from a pregnant woman contains a mixture of maternal and fetal DNA, many groups have pursued the isolation of fetal cells from the maternal circulation as a more definitive source for fetal DNA. Trophoblastic cells are uniquely fetal in origin but have proved difficult to isolate reliably because of the paucity of specific cell surface markers for sorting; another consideration is that 1% of pregnancies display chorionic mosaicism in which the placenta, but not the fetus, manifests cytogenetic abnormalities. Leukocyte fractions of fetal origin may be isolated from the maternal circulation, but the occasional persistence of cells in the CD34+ progenitor population from a prior pregnancy raises concern about the possibility of an erroneous result. The fetal nucleated erythrocyte has drawn attention as perhaps the cell best suited for prenatal diagnosis. These cells enter the maternal circulation in relatively high numbers (~1000:1 compared with fetal leukocytes) early in pregnancy, carry a full complement of fetal genomic DNA, and should not persist from prior pregnancies. These cells are just beginning to be isolated and studied systematically for their potential value in prenatal diagnosis.[59,60] Analysis of fetal RNA in maternal plasma also has opened the possibility of profiling fetal gene expression noninvasively.[61] Circulating DNA and RNA have also been investigated widely as markers for certain cancers that produce high levels of tumor-derived nucleic acids in the circulation or other body fluids.[62]

Fetal Microchimerism and Autoimmune Diseases

A report from France in 1998 examined archival skin biopsy material from 10 women with a skin rash, polymorphous eruption of pregnancy (PEP), who later gave birth to male infants.[59] Male DNA could be demonstrated in the skin of 6 of the 10 women with PEP but in none of an extensive set of control subjects. Investigators used microdissection techniques to separate dermis from epidermis and were able to show that both were positive for fetal DNA, strongly arguing that the PCR signal did not originate from trapped circulating blood cells; having no blood vessels, the epidermis' only cellular source is the dermis. Although a PEP rash typically regresses after parturition, this elegant study provided a precedent for the idea that chimeric fetal cells may infiltrate maternal tissue and cause a pathologic reaction.

The clear similarities between clinical features of chronic GVHD and adult-onset systemic scleroderma have long led to speculation that the conditions may be related. Although the etiology of scleroderma remains unknown, application

of molecular analyses is providing a convincing case that male cells are often present in the circulation and skin lesions of adult females with scleroderma. Although these allogeneic cells exist at very low levels, they have been found more often and in greater number among scleroderma cases than among control subjects.

Nelson and colleagues[63] described their findings in a study of 40 women, all of whom had given birth to at least one male infant. They studied 17 scleroderma patients, 16 healthy controls, and 7 sisters of the scleroderma patients. Histocompatibility between mother and fetus was assessed for an additional 21 patients, 32 controls, and their combined total of 105 offspring. Processing large volumes of whole blood for stochastic detection, these workers found a mean of 0.38 male genomic equivalents per 16 mL of whole blood among controls compared with 11.1 among women with scleroderma ($P = 0.0007$). In analyzing the histocompatibility data, they found that DR compatibility between mother and fetus was significantly more prevalent among scleroderma mother-child pairs than among control pairs, suggesting that DR compatibility facilitated MC while not providing an absolute requirement. They concluded that MC may be involved in the pathogenesis of scleroderma.

Artlett and colleagues[64] used a nonquantitative Y chromosome PCR to study peripheral blood and paraffin-embedded skin biopsy material from 69 women with systemic scleroderma. Thirty-two (46%) of the peripheral blood samples had demonstrable Y chromosome sequences compared with only 1 (4%) of 25 in normal women. FISH was used as an independent technique to confirm the PCR findings. Nucleated cells displaying a Y chromosome signal on FISH were demonstrable in all skin biopsy material found by PCR to contain Y chromosome sequences. The authors concluded that fetal antimaternal GVHD reactions may be involved in the pathogenesis of scleroderma for some female patients.

To follow up their earlier findings, Nelson's group used Y chromosome PCR to study subpopulations of peripheral blood lymphocytes highly enriched for CD3, CD19, CD14, and CD56/16 by flow-cytometric sorting.[65] Allogeneic cells were present in 12 of 20 women with scleroderma and 16 of 48 healthy control women ($P = 0.046$). No significant differences between immunophenotypic subsets were observed. The authors concluded that the finding of persistent, presumably fetal cells in these women suggested the existence of specific immunoregulatory pathways that allowed persistence while preventing effector function.

Blood transfusion has been identified, in some studies, as a significant risk factor for the development of rheumatoid arthritis,[66] and several groups have speculated that MC from pregnancy or transfusion may play a role in other "autoimmune" diseases, including rheumatoid arthritis and multiple sclerosis.[67] Much work remains to be done in the area of MC and autoimmune disease before a definitive causal relation is established, however. If MC cells are reproducibly present and etiologically involved, it is important to elucidate the mechanism by which so few allogeneic cells contribute to the pathogenesis of complex autoimmune disorders. Such work could lead to novel therapeutic strategies to suppress MC-mediated pathologic conditions.

The converse of fetal cells establishing MC in the mother occurs when maternal cells may cross the placenta to establish MC in the fetus and newborn. Many fewer data are available in this area. Evidence of maternal MC persisting to adult life has been published.[68] A few very small studies have examined the presence of maternal cells in aborted fetuses.[69,70] Recently, maternal cells have been associated with autoimmune syndromes in the newborn and children.[71–74] Much more work is needed in this interesting area and should be possible with improvements to the FISH technique and the availability of PCR assays for MC, such as InDel, which are not restricted to Y-chromosome or class II HLA and are not linked to the immune-response genes.

Microchimerism Associated with Solid Organ Transplantation and Stability of Pregnancy

In solid organ transplantation, MC has been attributed to engraftment of donor hematopoietic stem cells that reside in the transplanted organ.[11] After surgery, the donor cells migrate from the transplanted organ to recipient tissues throughout the body and also enter the circulation, where they may be detected as a minor cell population. In the transplant setting, establishment of MC has been viewed by some as a welcome sign of successful transplantation and a predictor of stable engraftment of the transplanted organ,[11] although others have questioned the validity of this assumption.[75] Fetal cell MC in maternal blood and tissues may similarly play a role in the establishment of immunologic tolerance that is required for successful pregnancy.[10,11,59] These observations have led to large-scale clinical evaluations of protocols in which allogeneic peripheral blood or bone marrow–derived cells are infused into patients undergoing solid organ transplantation[76,77] and into women with recurrent spontaneous abortions[78,79] in an effort to induce tolerance or reverse alloimmunization. Interest is found in development of strategies for establishing MC and immunologic tolerance to facilitate novel therapies with genetically modified allogeneic cells.[80] It has even been suggested that fetal progenitor cells may participate in the repair of injured maternal tissues.[81]

Transfusion-Associated Microchimerism

Studies by Schechter and coworkers[4,8] first demonstrated that transfusion of fresh blood is associated with transient appearance of donor leukocytes in recipients (detected by karyotype analyses) with associated recipient immune activation. In their seminal article, they[8] reported the transient appearance (days 3 to 7 after transfusion) of activated, proliferating lymphocytes in the circulation of recipients of fresh whole blood (but not frozen-deglycerolized blood). In a follow-up study, they[4] used karyotype analysis to show that, whereas the majority of proliferating lymphocytes were recipient cells, occasional donor lymphocytes were also detectable at the time of peak activation. On the basis of these data, they hypothesized that transfusion of blood containing viable donor lymphocytes results in a two-way proliferation reaction, representing an attempted GVH reaction by donor cells and graft rejection by recipient cells. Adams and colleagues[6] were among the first to deploy molecular methods for detection of donor leukocytes after transfusion. They studied 20 female patients undergoing major surgical procedures to monitor prospectively the presence of male donor leukocytes by using Y chromosome–specific PCR. The assays were nonquantitative analyses of total extracted DNA and demonstrated male sex–determining region Y (SRY) sequences up to 6 days after transfusion. A Dutch group reported a retrospective study of 21 renal transplant recipients by using

samples archived from donor-specific transfusions given before renal transplantation. They analyzed the presence of donor DNA by using nested PCR based on HLA-DRB1 polymorphisms, and found that in some patients, especially those receiving blood from a partially HLA-matched donor, donor leukocytes could be detected up to 8 weeks after transfusion.[7] Hutchinson[5,82] studied the persistence of leukocytes transfused to 14 neonates from their maternal donors and compared the results with those in 48 neonates transfused with banked blood whose donors were also sex discordant. By using karyotype to identify donor cells, this group found that maternal donor cells persisted for ≥2 years in 4 of the 14 neonates, whereas no donor cells were detectable in those receiving banked blood. It remained unclear whether histocompatibility or freshness of the transfused product contributed to these observations. In 2000, Vietor and colleagues[83] reported on 10 recipients of sex-mismatched intrauterine transfusion (IUT) of unmodified red blood cells (RBCs) up to 25 years earlier. Although all of the recipients were in good general health and none had evidence of TA-MC by sex chromosome in situ hybridization, 6 of 7 had evidence of TA-MC by Y-chromosome PCR. The authors concluded that IUT could result in persistence of donor cells for ≥20 years, but this was not associated with signs of immunologic aberration.

After the work of Schechter and coworkers cited earlier,[4,8] our group used quantitative allele-specific PCR methods developed specifically for the detection of TA-MC to characterize more precisely the kinetics of donor leukocyte persistence in transfused adult women undergoing elective orthopedic surgery.[84] Each patient had received fresh unmodified packed RBCs from a male donor; both Y chromosome and class II allele-specific PCR assays were used to detect and quantitate donor leukocytes. We demonstrated a 1000-fold expansion of allogeneic donor leukocytes in the recipient's circulation 3 to 5 days after transfusion.[84] The allogeneic cells were cleared from the circulation within 2 weeks. The finding was also corroborated in a canine transfusion model[85] by irradiation of the transfused blood, which abrogated the donor leukocyte expansion phase.

Building on these findings, our group has now documented high-level and long-lasting leukocyte MC among selected victims of traumatic injury who received a large number of fresh units of blood during their resuscitation.[3] Whereas very low levels of chimeric cells were observed in scleroderma patients or after transfusions in patients having elective surgery, in these trauma patients, 3% to 4% of peripheral blood leukocytes were of donor origin, and the donor cells persisted at high levels for as long as 2 years after transfusion. Analysis of lymphocyte subsets from these recipients by using immunomagnetic bead enrichment showed that both lymphoid and myeloid lineages were represented. In some cases, HLA typing of the donor combined with MC assays based on class II polymorphisms showed a single donor to be the sole source of the chimeric leukocytes. Figure 53–1 illustrates the transient expansion of donor leukocytes in elective orthopedic surgery patients versus the long-term high-level multilineage TA-MC, which becomes established in some trauma patients after transfusion.

In a more recent study of 45 transfused trauma patients, half had detectable, though low-level, TA-MC at hospital discharge, whether or not they had received exclusively leukoreduced blood products.[20] Immunologic characterization of these patients at hospital admission showed broad diminution of donor lymphocyte response to mitogen in all trauma patients compared with controls. Among transfusion recipients who went on to develop TA-MC, lymphocyte responsiveness was initially at lower levels and recovered less by the time of hospital discharge than among transfused patients who did not develop TA-MC. Here again, leukoreduction had no measurable effect on patient's lymphocyte responsiveness.[21] In a comprehensive recall of 646 of the 656 blood donors for these patients, mixed lymphocyte reactions (MLRs) were studied in both directions between the patients' pretransfusion lymphocytes and lymphocytes from each blood donor. For each patient who went on to become chimeric, a single donor could be identified whose lymphocytes showed bidirectional hyporesponsiveness with the patient

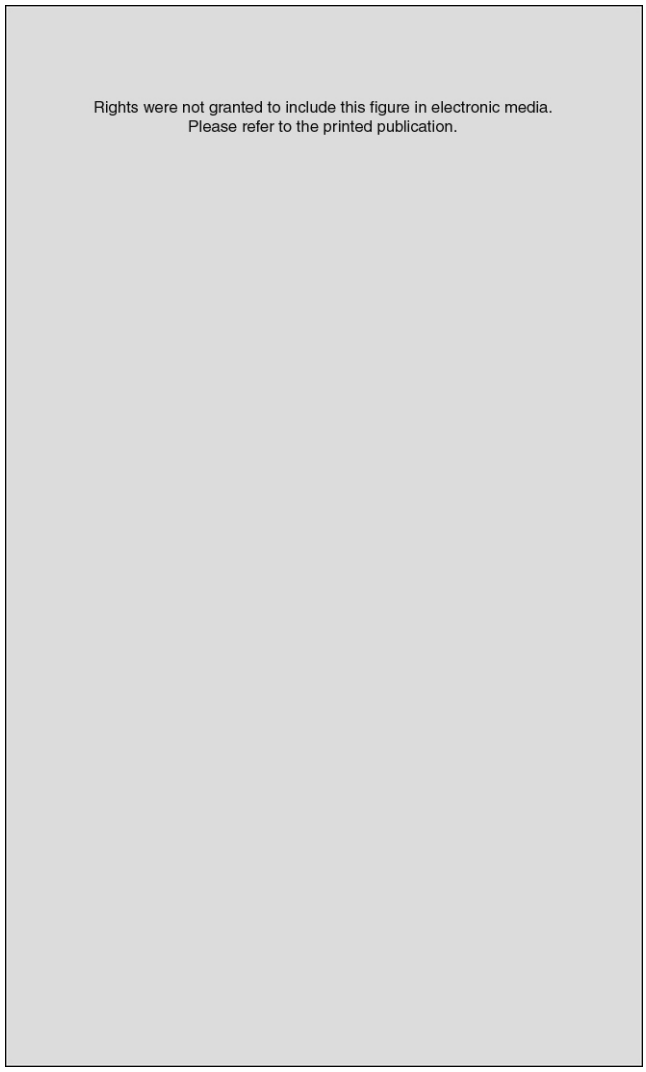

Figure 53–1 Representative survival kinetics of donor leukocyte subpopulations (including CD4, CD8, CD15, and CD19) after transfusion of female patients for (**A**) elective surgery and (**B**) severe trauma. Frozen whole blood samples were subjected to enrichment of $CD4^+$, $CD8^+$, $CD15^+$, and $CD19^+$ leukocytes subpopulations, followed by amplification, hybridization, and quantitation by using human Y chromosome–specific primers and probe. *Y*-axis: Concentration of donor cells per milliliter of recipient blood. *X*-axis: Time points when recipient blood samples were collected. (Data from Lee TH, Paglieroni T, Ohto H, et al. Survival of donor leukocyte subpopulations in immunocompetent transfusion recipients: Frequent long-term microchimerism in severe trauma patients. Blood 1999;93:3127–3139.)

who received that donor's unit. Although the microchimeric donor could not be definitively identified from the limited data available in these studies, in each case, the low-resolution HLA type of the implicated donor matched the DR type of the chimeric cells detected by PCR targeting HLA-DR alleles, suggesting strongly that the hyporesponsive donor was the source of the chimeric cells. Finally, when a subset of these patients was followed over the long term, five of the patients with low-level chimerism demonstrated subsequent evolution to high-level chimerism, apparently attributable to the same single donor.[19] The time course of TA-MC for these patients together with the multidonor MLR data are shown in Figure 53–2.

To date, no disease state has been convincingly associated with TA-MC, although it is important to remember that the modest number of patients in whom this phenomenon has been described have not been systematically examined for either clinical or laboratory stigmata of autoimmunity or other subtle health abnormalities. Sjögren's syndrome and vitiligo were reported in a woman with post-transfusion MC, and evidence has also been presented that chimeric donor cells may participate in tumor formation in both the maternal-fetal setting[86] and in the setting of kidney transplantation, where XY cytokeratin-positive cells representing male keratinocytes could be found in tumor cell nests among females transplanted with male kidneys who developed malignant and benign tumors.[87] Clearly, much remains to be learned about the basic biology and possible health effects of MC.

Murine Model of TA-MC

To pursue a more-detailed understanding of the immunologic mechanisms of TA-MC, which is difficult to study in the human population, transfusion models have been developed with both immunologically intact recipient animals and animals with specific knockouts of key immune system genes. Immunologically normal mice show clearance of donor leukocytes that is much slower than that in humans or dogs[88] and is dependent on intact $CD8^+$ T cells and alloantibody responses.[89] For both syngeneic and allogeneic transfusions, complete clearance of transfused donor cells occurs by 8 to 10 weeks in immunocompetent mice, with diminished persistence proportional to the duration of storage of the transfused blood at 4° C before infusion. Allogeneic donor WBC clearance appears to be biphasic, suggesting that both MHC-dependent and MHC-independent mechanisms may be involved.[90] With respect to the potential for transfer of lymphocyte function by transfusion, sensitivity to 1-chloro-2-4-dinitrobenzene (DNCB) could also be transferred, albeit transiently, by transfusion of fresh blood from a sensitized donor to a naive recipient.[90]

Recently, these observations have been extended by using murine transfusion experiments in which the recipients were represented by a series of specific immunologic knockouts representing functional lymphocyte defects, including depletion of T, B, and natural killer (NK) cells, as well as defects in macrophage function and in expression of MHC class II molecules.[91] Findings from these experiments are summarized in Figure 53–3. The data indicate that for long-term TA-MC to become established in the murine setting, higher degrees of recipient immunocompromise are required, with increasing MHC disparity between donor and recipient. Of note, knockout mice that develop donor microchimerism had persistence of all lymphocyte immunophenotypes and evidence of functional immunity derived from the donors, suggesting therapeutic potential for TA-MC.

GRAFT-VERSUS-HOST DISEASE

The current concept of GVH reactions was formulated in the 1950s when it was recognized that spleen cell transplants in irradiated mice initially resulted in recovery of the animals from radiation injury and marrow aplasia but led to fatal "secondary disease" and "runting syndrome," characterized by wasting, diarrhea, skin lesions, and liver abnormalities.[92] In the 1960s, the term GVHD was coined, and Simonsen[93] and later Billingham[94] defined minimum criteria for the condition: (1) presence of immunocompetent cells in the graft, capable of reacting against the recipient; (2) major histocompatibility differences between donor and recipient; and (3) inability of the recipient to reject donor cells. With the exception of the second criterion, which has been revised to include inappropriate recognition of self-antigens (i.e., autoimmunity),[95,96] Billingham's criteria remain the basis for our understanding of the disease process in GVH reactions. Extensive research efforts have since clarified the mechanisms and conditions that lead to GVHD, although mechanistic details and causal relations of the multifactorial process are still incompletely understood.[96–98]

Clinical GVHD was first described by Shimoda[99] in 1955 as "postoperative erythroderma" in a case report of what was later identified as TA-GVHD. The first accounts of recognized TA-GVHD were published in the mid-1960s by Hathaway and associates.[100,101] Subsequently, TA-GVHD was described in immunosuppressed patients[102] and later also in immunocompetent transfusion recipients who were recognized as being at risk because of a relatedness in HLA antigens to the blood donor.[103,104] TA-GVHD remains a rare but distinct threat to at-risk recipients because of its severe course and resistance to therapy. Recognition of susceptible recipients who can be protected by gamma-irradiation of blood before transfusion is essential.

GVHD after transplantation was first recognized in 1959 in a report of "secondary-like disease" afflicting leukemia patients who had received bone marrow transplants.[92] We now recognize acute GVHD and chronic GVHD as clinically distinct entities in transplant patients, although some overlap may occur between the two conditions.[27,28] GVHD is most common in bone marrow transplant recipients but also occurs in recipients of solid organ transplants, particularly liver transplants.[105,106] Disease severity is extremely variable, but both acute and chronic GVHD after transplantation are reasonably responsive to a variety of immunosuppressive and immunomodulatory therapy protocols that have been developed.[24]

Pathophysiology

The simplified model of pathogenesis that has emerged since the pioneering studies of GVHD in the 1950s suggests that immunocompetent donor lymphocytes that are not cleared because of a compromised host immune system go on to proliferate in the recipient. This is followed by attack and destruction of host tissues in target organs, including liver, intestines, skin, and, perhaps, lung.[96] Supporting the validity of this model in TA-GVHD is a positive correlation between the number of transfused viable donor lymphocytes and the degree of immunosuppression in the host on the one side and the likelihood of occurrence and severity of TA-GVHD on the other.[92] The threshold dose of lymphocytes to incite TA-GVHD in humans is not precisely known, but case reports

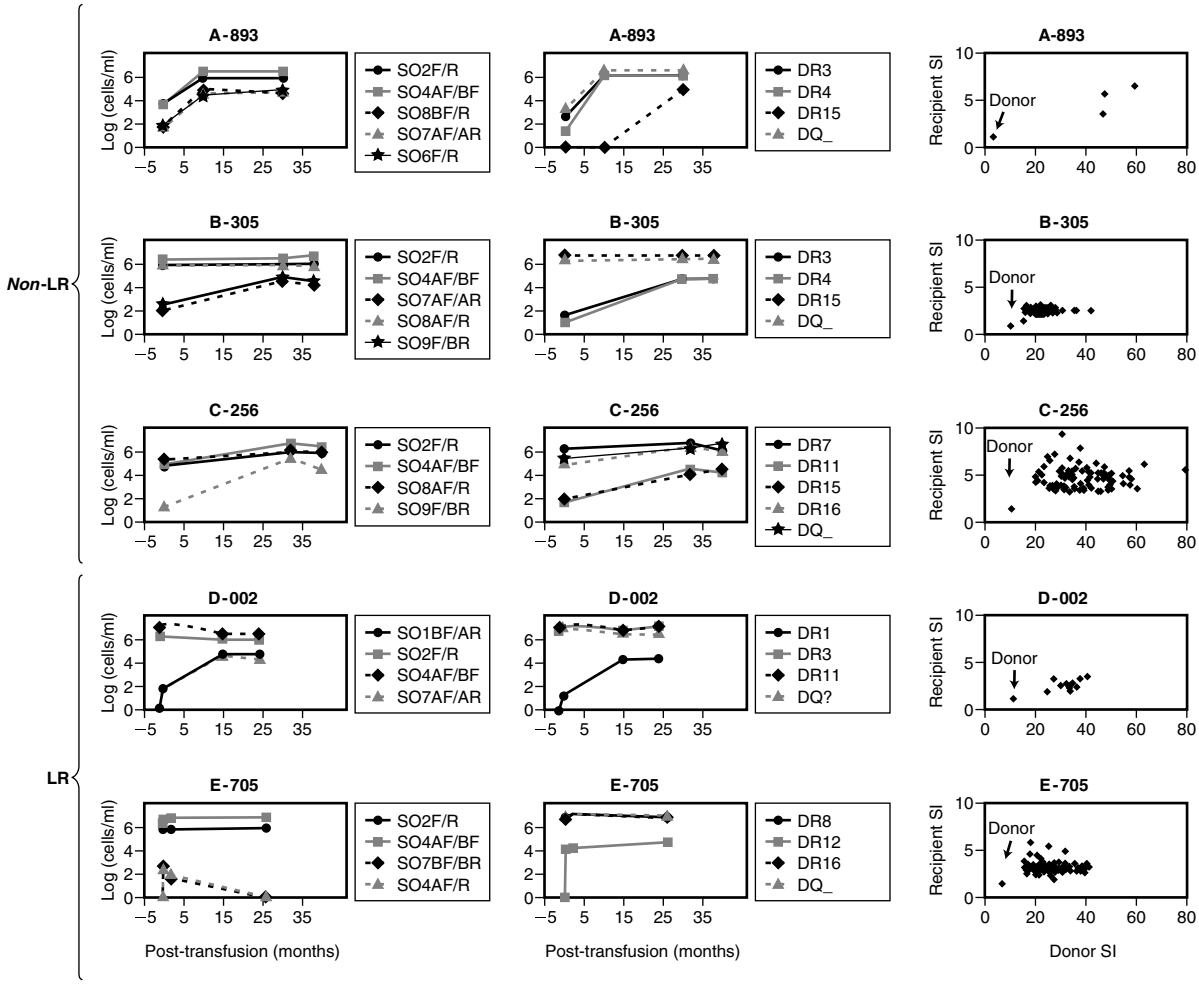

Figure 53–2 Donor leukocyte and mixed lymphocyte reaction (MLR) results of the five patients with long-term microchimerism (MC). The quantitative degree of MC (log-scale) over time in each of the patients with long-term MC is plotted in the first two columns, for InDel and HLA-DR, respectively. The concentration of the major and minor alleles, as well as HLA-DQa, a measure of genomic DNA, input per reaction, is plotted against time. The *Y*-axis is concentration (in number of target sequence per milliliter of total whole blood), and the *X*-axis is time (in months). The first three subjects received non-LR blood products, whereas the last two received exclusively LR blood products. The third column represents the corresponding donor-versus-recipient MLR for each of the five subjects. Microchimerism, indicated by an *arrow* corresponding to the implicated donor, was observed when the donor and the recipient stimulation indices were mutually low. (Data from Lee TH, Paglieroni T, Utter GH, et al. High-level long-term white blood cell microchimerism after transfusion of leukoreduced blood components to patients resuscitated after severe traumatic injury. Transfusion 2005;45:1280–1290.)

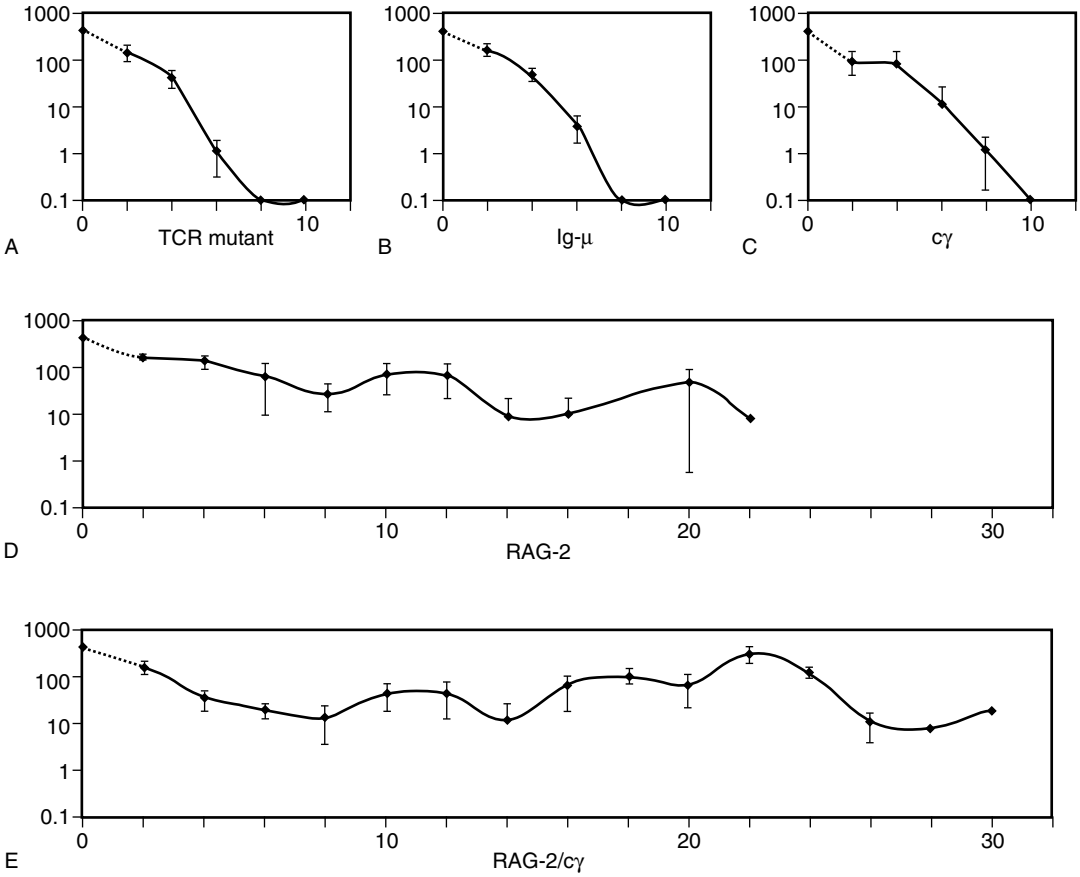

Figure 53–3 Donor leukocyte (DL) clearance in allogeneic recipients. **A,** DLs cleared at 8 weeks after transfusion to recipients lacking functional T cells. **B,** DLs cleared at 8 weeks after transfusion to recipients lacking mature B cells. **C,** DLs cleared at 10 weeks after transfusion to recipients with defective common-g receptor (receptors for cytokines [i.e., interleukin-2, IL-4, IL-7, IL-9 and IL-15]). These recipients lack natural killer (NK) cells but produce a small number of B and T cells. **D,** Proliferation of DLs after 22 weeks after transfusion to mice lacking mature B and T cells. **E,** Proliferation of DLs at 30 weeks after transfusion to recipients lacking B, T, and NK cells. (Data from Lee TH, Wen L, Montalvo L, et al. Minimum conditions of major histocompatibility complex compatibility and recipient immune compromise required to establish donor white blood cell persistence in a murine transfusion model. Transfusion 2005;45:301–314.)

suggest that leukoreduction by current filtration (usually to $<5–6 \times 10^6$ WBCs per 300 mL of blood component) is not sufficient to prevent the disease.[107–109]

Occurrence of TA-GVHD in immunocompetent recipients has been explained by a so-called one-way HLA match in which the donor cells are homozygous for an HLA type for which the recipient is heterozygous.[104] As a consequence, the recipient immune cells do not recognize the donor cells as foreign and fail to mount an immune response that would normally clear the donor cells. The latter, however, respond to the mismatched haplotype and incite the GVH reaction, which proceeds as aggressively as in immunocompromised patients.

Refinements in the basic model suggest a complex interaction of recipient and host immune cells and emphasize the notion that the latter is not a mere passive bystander but participates in and maintains the GVH reaction through dysregulated cell activation and cytokine release. Recipient T-helper subset 1 (Th1) cytokines interleukin-2 (IL-2) and interferon-β and proinflammatory cytokines IL-1 and tumor necrosis factor-β (TNF-β) appear to promote the deleterious effects of GVH, whereas Th2 cytokines IL-4 and IL-10 are thought to have a downregulating effect.[97]

New insights have also been achieved into the roles of lymphocyte subpopulations in the pathophysiology of GVHD. A mouse model provided evidence that T-cell subsets play opposite roles in the disease process, with recipient CD8 cells providing protection, whereas recipient CD4 cells promote a GVH response.[110,111] According to the authors, patients with impaired CD8 and NK cell function are at increased risk for TA-GVHD, especially if they receive HLA haploidentical blood. Interestingly, this hypothesis provides one explanation for the clinical observation that human immunodeficiency virus (HIV)-infected persons do not develop GVHD after allogeneic transfusions despite impaired cellular immunity. In these patients, CD4 counts decrease early, but CD8 counts remain high until late in the disease course. Infection of infused donor CD4 cells by HIV, followed by attack on the infected cells by cytolytic CD8 cells, may provide an additional explanation for the apparent absence of GVHD in patients with acquired immunodeficiency syndrome (AIDS).[112] Demonstration of rapid disappearance of donor leukocytes (from transfused cellular blood components) in late-stage AIDS patients has confirmed the notion that HIV infection is not associated with an increased risk of TA-GVHD, despite profound cellular immunodeficiency.[113] The precise role of recipient T-cell subsets in susceptibility to GVH reactions remains controversial, however, with others maintaining that reactive recipient CD8 cells are required for the development of GVHD.[114]

With regard to the effector cells that cause tissue damage in GVHD, evidence from studies of patients with TA-GVHD

suggests that donor T cells participating in the disease process are clonally restricted in expression of T-cell–receptor repertoires[115] and are composed of a variety of CD4- and CD8-positive clones that may cause tissue damage through different mechanisms, including direct and indirect cytotoxicity.[116] The latter finding may explain the often characteristically sparse lymphocytic infiltrate of target tissues in GVHD. Indirect cell lysis may occur through an apoptosis-inducing mechanism or through cytokine release (TNF-β, IL-1) followed by attraction of platelets and neutrophils, causing cell damage by release of free radicals and elastases.

Clinical Presentation

Patients with TA-GVHD typically are first seen within 7 to 10 days of the transfusion with fever, a characteristic reddish raised rash spreading from trunk or face to the extremities, evidence of hepatitis, watery diarrhea, and nonspecific signs including anorexia, nausea, and vomiting.[25,117] The diarrhea may be profuse, and the skin lesions may progress to bullous lesions and generalized erythroderma. The development of pancytopenia caused by immune destruction of host marrow cells distinguishes TA-GVHD from GVHD after hematopoietic stem cell transplantation and is the usual cause of death of hemorrhage and overwhelming infection. Most patients die within 1 to 3 weeks after the onset of clinical symptoms.[103] In neonates, symptoms appear later, approximately a month after transfusion, and the disease tends to run a more prolonged course with survival for up to 3 months.[117] The naive T-cell population in infants and a different cytokine milieu favoring interferon-β over IL-2 may be responsible for the delayed response. Few patients survive TA-GVHD, although spontaneous recovery or development of a chronic form of GVHD has been reported.[117–119]

Epidemiology

TA-GVHD is rare in unselected U.S. transfusion recipients and has been almost exclusively observed in immunocompromised patients.[120] A list of specific immune-deficient states that have been associated with either clear, probable, or no specific risk for the complication is shown in Table 53–4. A special situation is treatment with purine analogs, particularly fludarabine. The drug induces profound, long-lasting lymphopenia, involving both T and B cells, and has been associated with at least 10 published cases of TA-GVHD. In 7 of the 10 cases, fludarabine was given for treatment of chronic lymphocytic leukemia (CLL), which resulted in listing this clinical constellation as one that clearly carries risk. However, occurrence of TA-GVHD in two patients with other hematologic conditions (acute myeloid leukemia and B-cell lymphoma) and a third recent case in a patient with lupus nephritis, suggests that fludarabine treatment in itself or in combination with alkylating agents confers risk independent of an association with CLL.[121]

Conversely, the potential for TA-GVHD in patients with no or only mild immunodeficiency is demonstrated by more than 200 documented cases in Japan,[103] where incidence rates as high as 1 in 660 patients undergoing cardiovascular surgery were reported.[122] Greater genetic homogeneity of the Japanese population and frequent use of unirradiated fresh whole blood from related donors in the past were thought to be the primary reasons for the surprisingly frequent occurrence of TA-GVHD in this country.[123,124] After adoption of and adherence to strict guidelines for prevention of the condition (including universal irradiation of cellular blood components), the number of new cases in Japan has decreased dramatically.[125]

Reports of relatively high rates of TA-GVHD have also come from other geographic areas with genetically homogeneous populations.[126] Estimates of the risk of TA-GVHD based on genetic similarities in HLA haplotype frequencies between random blood donor-recipient pairs yielded a potential rate of 1 in 17,700 to 1 in 39,000 among whites in the United States; the risk in Japan was projected to be 1 in 1600 to 1 in 7900. Directed donations between parents and children increase the risk of histocompatibility from 10- to 20-fold.[127,128]

Diagnosis

Given the rarity of the disease, the diagnosis of TA-GVHD may be missed and is often not made until late in the course or postmortem unless a high degree of suspicion exists.[128] Other diagnoses such as drug reaction or infections are usually considered first. Routine laboratory studies are not helpful for an etiologic diagnosis. Histologic findings on skin, liver, or intestinal biopsies may suggest the diagnosis of TA-GVHD but are not pathognomonic. The only definitive method of diagnosis is the identification of donor-derived lymphocytes in the circulation or tissues of the affected patient. This may be accomplished by detailed HLA typing, cytogenetic analysis, or studies of genomic markers capable of reliably identifying donor and recipient cells.[124,129,130] For female recipients, detection of Y-chromosome regions by

Table 53–4 Patient Groups at Risk for Developing Transfusion-Associated Graft-versus-Host Disease

Clear Risk
Patients with selected immunodeficiencies
Congenital immunodeficiencies
Hodgkin's disease
Chronic lymphocytic leukemia (CLL) treated with fludarabine*
Newborns with erythroblastosis fetalis
Recipients of intrauterine transfusions
Recipients of hematopoietic stem cell transplants
Recipients of blood products donated by relatives
Recipients of human leukocyte antigen (HLA)–selected (matched) platelets or platelets known to be homozygous
Probable Risk
Patients with other hematologic malignancies
Patients with solid tumors treated with cytotoxic agents
Recipient-donor pairs from genetically homogeneous populations
Premature and possibly full-term neonates
No Defined Risk
Patients with acquired immunodeficiency syndrome (AIDS)
Patients taking immunosuppressive medications.

*Treatment with fludarabine (and perhaps other purine analogs) in itself, particularly in conjunction with alkylating agents, may be a clear risk, independent of combination with CLL. See discussion in Epidemiology section.

Data from Webb IK, Anderson KC. Transfusion-associated graft-versus-host disease. In Anderson KC, Ness PM (eds). Scientific Basis of Transfusion Medicine, 2nd ed. Philadelphia, WB Saunders, 2000, pp 420–426.

PCR has been used to confirm TA-GVHD by documenting circulating male cells.[129,131] In seeking donor-derived genotypes to support the diagnosis of TA-GVHD, it is critical to consider the PCR amplification strategy; a strategy with limited primer specificity or inadequate sensitivity could result in a false-negative chimerism assay, as discussed earlier in this chapter (see Table 53–3).[36]

Therapy

Immunosuppressive therapy with corticosteroids, antithymocyte globulin, cyclophosphamide, methotrexate, and cyclosporine, alone or in combination, which is usually able to influence TA-GVHD,[27,28] is generally ineffective in TA-GVHD.[26,97,131] Hematopoietic stem cell transplantation has been attempted successfully in rare instances,[132] and infusion of leftover autologous hematopoietic progenitor cells has resulted in recovery in a single reported case.[133]

Because of the small number of case reports in which treatment resulted in recovery,[118,134] and uncertainty about whether a milder form of the disease contributed to the success, consensus treatment guidelines have not been formulated.

Prevention

Gamma-irradiation of blood components containing viable lymphocytes is virtually 100% effective in preventing TA-GVHD, although rare failures have been reported with irradiation doses considered suboptimal today.[135–137] Irradiation prophylaxis is recommended for all whole blood, RBC, platelet, and granulocyte units transfused to patients at risk.[138] Irradiation prevents proliferation of lymphocytes through crosslinkage of DNA.[139] The required dose is 25 Gy to the mid-plane of the blood container with a minimum of 15 Gy to any point of the irradiated field.[138] The Food and Drug Administration further mandated that the maximum dose not exceed 50 Gy.[131] In this dosage range, irradiation is considered safe, with unlikely harm to the recipient of the treated component.

Adverse effects of irradiation on therapeutic blood components include a moderate decrease in survival of RBCs[140] and leakage of potassium from intracellular stores.[141,142] The allowable storage period for irradiated RBC units has therefore been reduced to 28 days,[138] and caution is advised in administering stored irradiated RBC units to recipients at risk for ill effects of hyperkalemia.[143] These include primarily neonates and premature infants with renal failure or those who receive large-volume transfusions, especially if administered through central venous catheters, or treatment with extracorporeal membrane oxygenation through central venous catheters. Platelets do not appear to be affected by the recommended radiation dose during routine 5-day blood-bank storage,[144,145] and no reduction in storage time is necessary. Frozen thawed RBC units, fresh frozen plasma (FFP), and cryoprecipitate are widely viewed as "acellular" blood components, and no documented cases of TA-GVHD after administration of these components have been reported[131]; irradiation is therefore not currently recommended. TA-GVHD has, however, occurred after transfusion of fresh liquid plasma that had never been frozen,[146] and some believe that FFP may contain sufficient viable lymphocytes to be of concern.[147,148] This issue is currently under investigation. The reader is referred to Chapter 28 for a more detailed discussion of technical, procedural, and regulatory aspects of blood component irradiation.

Experimental methods of lymphocyte inactivation for TA-GVHD prophylaxis include ultraviolet B (UVB) irradiation[149] and photochemical treatment with UVA-activated psoralens.[150] The latter approach, which has been developed for pathogen inactivation in platelet and plasma units and is being evaluated in clinical trials, may be at least equally effective in preventing lymphocyte response to immunologic stimulation and proliferation.[150,151]

Patients at Risk Who Should Receive Transfusion-Associated GVHD Prophylaxis

Because TA-GVHD may occur in immunocompetent individuals, any transfusion recipient may be considered at risk, and identification of defined risk groups may provide a false sense of security to those not included in the at-risk groups. However, unless all blood components are routinely irradiated, the categorization of patients who are at particular risk on the basis of experience is useful and practically important. Table 53–3 categorizes patient groups according to risk level for developing TA-GVHD. Irradiation of cellular blood components is mandatory for patient groups with clear risk; for others, irradiation may be considered, but no universal consensus has been reached.[138]

SUMMARY

Microchimerism has been recently described in association with a number of specific allogenic exposures including pregnancy, twinning, transplantation, and blood transfusion. Despite the research reports reviewed here, the prevalence and magnitude of MC in healthy populations and the precise relation between MC and specific allogeneic exposures, such as pregnancy and transfusion, has not yet been studied systematically. In the setting of traumatic injury, leukocytes from a single blood donor may persist months to years at a level that increases over time to as much as 3% to 4% of the recipient's total circulating leukocytes. This TA-MC phenomenon may affect 50% of patients transfused for traumatic injury if measured at hospital discharge. In long-term follow-up, limited data suggest that 1 in 5 of these patients will go on to develop high-level, persistent TA-MC. It is important for future research to determine whether persistent TA-MC occurs in other clinical settings where tissue injury is prominent, the immunologic mechanisms involved, the extent of hematopoetic and immunologic engraftment, and, perhaps most important, whether it represents a harmful or beneficial consequence of blood transfusions. The latter question is especially relevant, as viable donor lymphocytes from transfused cellular blood components may on rare occasions cause an almost uniformly fatal TA-GVHD. Unlike GVHD associated with transplantation of organs or hematopoietic stem cells, which tends to be associated with a more manageable acute and/or chronic course, donor lymphocytes in TA-GVHD prominently attack recipient bone marrow stem cells, resulting in cytopenias and a rapidly lethal course. As TA-GVHD is rare, it may be overlooked. Diagnosis is based on demonstrating infiltrating donor-derived lymphocytes in recipient tissues. Treatment has rarely been successful, emphasizing the importance of prophylaxis. Gamma-irradiation of cellular blood components that render donor lymphocytes incapable

of proliferation remains the only reliable and widely available method for prevention. Although some donor/recipient constellations are clearly associated with higher risk of TA-GVHD, it is difficult to identify all recipients who may be predisposed to TA-GVHD and who therefore should receive irradiated blood components. It is hoped that further research in donor-recipient factors that allow and promote microchimerism and GVHD will provide critical insight into better care of transplant patients and increased safety of transfusion recipients.

C. Therapeutic Apheresis

Chapter 54

Therapeutic Apheresis: Basic Principles and Practical Aspects

Peter A. Millward • Nicholas Bandarenko • Mark E. Brecher

INTRODUCTION

The age-old notion of "bad blood," which was the basis of blood letting, ultimately evolved to the more sophisticated blood-separation techniques of today. Apheresis, a word of Latin derivation (from the word *aphaeresis,* a withdrawal),[1] emerged in the early 20th century. In 1914 at Johns Hopkins Hospital, Roundtree, Abel, and Turner used "plasmapheresis" to mitigate symptoms after bilateral nephrectomy in dogs. Although these experiments were associated with deaths (due to apparent overbleeding and hemorrhage), the improvement in the clinical condition of the animals successfully treated was "marked." The term *apheresis* has since been generalized to refer to the separation of blood into its components, removal of one component, and return of the remainder. Thus *leukapheresis* means the removal of leukocytes, and *erythrocytapheresis* means the removal of erythrocytes. Alternative terminology such as plasma exchange and erythrocyte exchange are frequently used interchangeably for plasmapheresis and erythrocytapheresis. Some authors have suggested that the term *plasma exchange* be reserved for low-volume procedures involving no more than 500 to 600 mL of plasma, and *plasmapheresis,* for large-volume procedures, but these terms are frequently used interchangeably.

In the 1950s, therapeutic application of these techniques emerged for the treatment of patients with hyperviscosity syndromes.[2–6] An acceleration in the interest and development of apheresis applications had to await the arrival of automated cell separators in the 1970s.[7,8] The past 3 decades are testimony to major advances in apheresis including equipment, automation, plastics, microprocessors, and separation techniques. Today, apheresis has become standard of care for a diversity of diseases. These are summarized in Table 54–1. The relative frequency of therapeutic apheresis procedures by type is illustrated in Figure 54–1.

It is intriguing that, even today, requests for therapeutic apheresis inevitably arise out of desperation or ignorance in diseases and conditions when therapeutic options have been exhausted. However, apheresis procedures are not without risk or cost. One must be judicious in their application and strive to do no harm. Objective evidence provided by published clinical and basic research provides the rationale for therapeutic apheresis. Nevertheless, we must be cognizant that clinical situations do arise in which little or no literature is available to provide guidance. Under such circumstances, a reasoned collegial approach, weighing the potential risks and benefits for the patient, is mandatory, along with a full, informed consent.

MODELING OF APHERESIS KINETICS

Volume Exchanged

The choice of a volume of blood to be exchanged is based on the kinetic modeling of apheresis. Kinetic modeling of apheresis exchange is generally based on an isolated one-compartment intravascular model. This model assumes that the component removed is neither synthesized nor degraded substantially during the procedure, that it remains within the intravascular compartment, and that instantaneous mixing occurs. In the short term, these assumptions work relatively well when applied to solutes that are located predominantly in the intravascular compartment, such as immunoglobulin M (IgM) and red blood cells (RBCs); they work less well for proteins such as IgG, which are predominantly extravascular in distribution. The intravascular distribution of IgG, IgA, IgM, albumin, and fibrinogen is approximately 45%, 42%, 76%, 40%, and 80%, respectively.[10]

For continuous-flow plasma exchange, the removal of plasma or solute can be described by the same differential equation that applies to isovolemic hemodilution:

$$\frac{dS}{dV_{ex}} = \frac{-S}{PV}$$

where S is the solute concentration, V_{ex} is the volume exchanged, and PV is the plasma volume. This equation can be integrated to yield:

$$V_{ex} = PV \times \ln (S_i/S_f)$$

where S_i is the initial solute concentration and S_f is the final solute concentration.

This equation can be modified to yield:

$$\text{Fraction remaining} = S_f/S_i = e^{-V\text{ex}/PV}$$

For intermittent flow, if the replacement is given after the removal of the plasma, after N repetitions of plasma removal, the remaining fraction of the plasma (and the analyte in question) is given by the following equation:

$$\text{Fraction remaining} = [(PV - \text{volume removed}) / PV]^N$$

If the replacement is given before the removal of the plasma, after N repetitions of plasma removal, the remaining fraction

Category I, standard acceptable therapy; Category II, sufficient evidence to suggest efficacy, usually as adjunctive therapy; Category III, inconclusive evidence of efficacy or uncertain risk-benefit ratio; Category IV, lack of efficacy in controlled trials.

Modified from Smith JW, Weinstein R, Hillyer K. Therapeutic apheresis: a summary of current indication categories endorsed by the AABB and the American Society for Apheresis. Transfusion 2003;43:820–822.

of the plasma (and the analyte in question) is given by the equation:

$$\text{Fraction remaining} = [\text{PV}/(\text{PV} + \text{volume removed})]^N$$

Because of the initial hemodilution that occurs if the replacement is given before the removal of the plasma, for each cycle of plasma removal, the fraction remaining is less than if the replacement had been given only after each repetition of plasma removal.

A comparison of continuous versus intermittent-flow plasma exchange is illustrated in Figure 54–2.

Calculations for RBC exchanges, although somewhat more complicated, can be achieved in a similar manner. In this case, total blood volume is substituted for plasma volume, and the solute of interest is either the hemoglobin concentration or the hematocrit. For example, continuous-flow apheresis can be used for a sickle cell patient who has a total blood volume (TBV) of 5 L and a hematocrit of 32%. If it is assumed that the patient has 100% hemoglobin S and the therapeutic goal is to decrease the percentage of hemoglobin S to 30% while maintaining the patient's hematocrit at 32%, the amount of blood that must be processed would be given by

$$V_{ex} = 5000\ \text{mL} \times \ln(100\%/30\%) = 6020\ \text{mL}$$

The volume of RBCs needed for replacement to maintain the patient's hematocrit at 32% throughout the procedure would be

$$6020\ \text{mL} \times 0.32 = 1926\ \text{mL}$$

If it is assumed that a typical allogeneic unit contains 200 mL of RBCs or RBC mass, then 10 units (1926 RBC mL/200 mL per unit = 9.6 units) would be needed.

An alternate approach takes into account that a 70% removal involves the processing of 1.2 times the RBC volume and dividing by the typical allogeneic unit RBC volume. In this case, it would be (5000 mL × 0.32 × 1.2)/200 = 9.6 units.

Timing

The timing of exchanges is generally chosen based on a balancing of the need to allow the solute or cell of interest to re-equilibrate into the vascular space and the desire to minimize the risk of bleeding with dilutional coagulopathy.

Efficiency of Immunoglobulin Removal

In the case of IgG, in which only 45% of the IgG lies within the intravascular space, a 1 plasma volume exchange would be expected to remove 63.2% of the intravascular IgG but only 28.4% of the total body IgG. Re-equilibration of the intravascular IgG with extravascular IgG typically occurs within 2 days and results in a substantial increase in the intravascular IgG level. For example, a patient with an IgG level of 10 g/L would

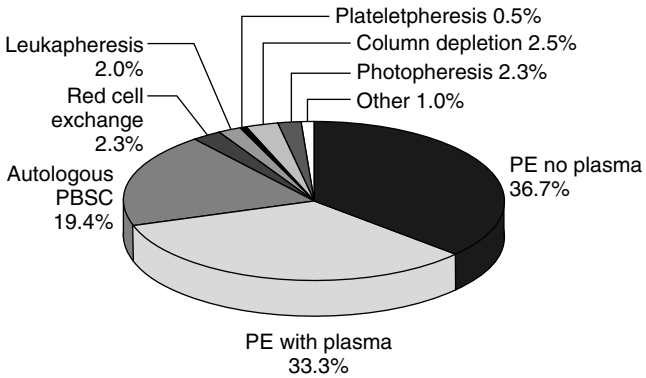

Figure 54–1 Relative frequency of therapeutic procedures by type, based on data from 18 institutions in the United States encompassing 3421 procedures. Table 54–2 **Demonstration of the Apheresis Kinetics for Six Plasma Exchanges with a Theoretical Initial Intravascular IgG Level of 10 g/L in a Patient with a Blood Volume of 5 L, a Hematocrit of 40%, Receiving 1 Plasma Volume Exchange**

	Plasma IgG (g/L)	Intravascular IgG (g)	Extravascular IgG (g)	Total body IgG (g)
Preprocedure	10	30	36.67	66.67
1st 1PV TPE	3.68	11.04	36.67	47.71
1st Re-equilibration	7.16	21.47	26.24	47.71
2nd 1PV TPE	2.63	7.90	26.24	34.14
2nd Re-equilibration	5.12	15.36	18.78	34.14
3rd 1PV TPE	1.88	5.65	18.78	24.43
3rd Re-equilibration	3.66	10.99	13.44	24.43
4th 1PV TPE	1.35	4.05	13.44	17.48
4th Re-equilibration	2.62	7.87	9.62	17.48
5th 1PV TPE	0.97	2.90	9.62	12.51
5th Re-equilibration	1.88	5.63	6.88	12.51
6th 1PV TPE	0.69	2.07	6.88	8.95
6th Re-equilibration	1.34	4.03	4.92	8.95

have the intravascular IgG level reduced to 3.68 g/L, but after equilibration, this level would be expected to increase to 7.16 g/L (Table 54–2). Increasing the volume of plasma exchanged from 1 plasma volume to 1.5 plasma volumes is associated with only a modest increase in IgG removal (Fig. 54–3). Frequently, an overall 70% to 85% reduction of IgG is chosen as a goal of serial TPE therapy. A short-term reduction of 70% in the titer of anti-acetylcholine receptor in myasthenia gravis patients is generally associated with clinical improvement.[11]

To achieve a 70% to 85% reduction in intravascular IgG (after re-equilibration and ignoring synthesis and catabolism), one would in theory require four 1 plasma volume exchanges. Turnover of IgG is relatively slow, with an approximate half-life of 21 days, but rapid rebound frequently occurs, and sustained reductions of IgG cannot be achieved unless plasma exchange therapy is combined with immunosuppression. In practice, a 70% to 85% reduction in IgG can frequently be achieved with 5 to 6 plasma exchanges over 14 days *when combined with immunosuppression.* Despite the more-rapid synthesis of IgM (half-life of 5 to 6 days), comparable reductions of IgM are seen with the same number of exchanges, and rapid total body depletion of IgM (versus IgG) can be more effectively achieved because of the predominant intravascular distribution of IgM.

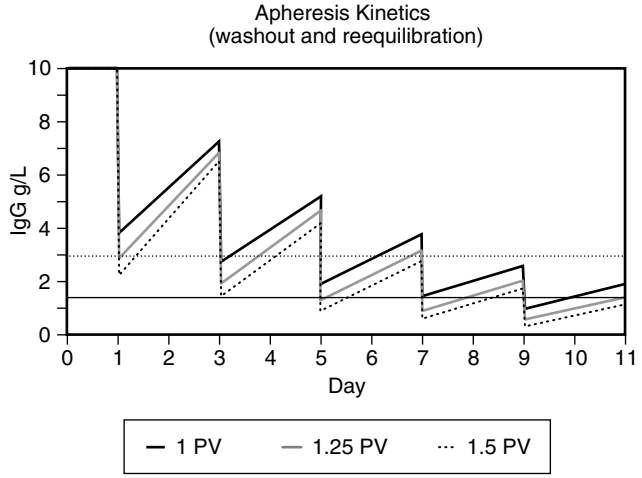

Figure 54–3 Theoretic reduction of immunoglobulin G (IgG) after plasma exchange of 1, 1.25, and 1.5 plasma volumes and after re-equilibration of total body IgG. The *solid line* indicates an 85% reduction, and the *dashed line*, a 70% reduction. The absolute reduction in IgG is reduced with each subsequent exchange. Calculations assume no degradation or synthesis of IgG and re-equilibration of IgG at 2 days.

Reductions of IgG beyond 70% to 85% are difficult to achieve as the absolute reduction in IgG with each subsequent plasma exchange is reduced (see Fig. 54–3). For six successive 1 plasma volume exchanges, the decrease in IgG (immediately before to after procedure) in a patient with an initial IgG level of 10 g/L would be 6.3, 4.5, 3.2, 2.3, 1.7, and 1.2 g/L, respectively (see Table 54–2).

Thus the number of exchanges performed takes into account both the diminishing efficiency of removal associated with serial exchanges and the level that is generally associated with clinical efficacy.

OVERVIEW OF TECHNOLOGY

Current apheresis instrumentation involves the separation of blood components, segregation of the component being targeted by using on-line automated technology, and delivery of the remaining components back to the individual donor or patient. The use of temporary anticoagulation (with citrate alone or in combination with heparin) and disposable sterile plastic tubing sets enable these basic steps to be accomplished by a variety of instruments, which typically accommodate flow rates of 30 to 150 mL/min from either central or peripheral venous access.[12] Variations in the design of apheresis separators affects their efficiency of collection and removal and influences their suitability for specific donor or therapeutic applications. Currently licensed automated apheresis equipment separates blood components by either centrifugation or filtration and can operate with either continuous or intermittent flow. Table 54–3 summarizes the current technology.

Differential Centrifugation

Because of differences in density, anticoagulated whole blood separates into components when centrifuged. Mature RBCs have the greatest relative density, followed by neocytes, granulocytes, mononuclear cells (including lymphocytes, peripheral blood progenitor cells), and then platelets

Table 54–3 **Summary of Current Apheresis Technology**

Manufacturer	Instrument	Type	Flow	Access	Donor/ Therapeutic	Procedure/ Products
Haemonetics	V-50	C, bowl	I		D, T	PL
	PCS/PCS-2	C, bowl	I		D	PL

and finally plasma. Whole blood pumped into the apheresis separator enters a rotating bowl, chamber, tubular rotor, or a belt-shaped channel. Once equilibrium is reached, the desired fraction can be selectively removed. An optical sensor may aid in maintaining the interface between components, and all systems have a mechanism to prevent twisting of the tubing that feeds the separation chamber.

With intermittent flow (discontinuous flow), whole blood is processed in batches (refer to Fig. 54–4). With each cycle, the centrifuge device is filled; separation occurs until the dense component fills the separation container. Then processing is interrupted to empty the device. Haemonetics, Inc. (Braintree, MA) manufactures the most widely used currently licensed intermittent-flow centrifugation devices. These separators are useful for collection of plasma, platelets, leukocytes, or RBCs by a single or double venous access.

The Latham bowl is the centrifuge chamber in Haemonetics models: V50, MCS, and MCS Plus. This conical chamber has a stationary stem joined to the rotating bowl by a rotating seal. Blood enters the bottom (stationary stem) and rises between two conical surfaces. The centrifugal forces cause a vertical interface between RBCs (outside layer) and plasma (inside layer). Plasma, being of lower density, eventually exits the top of the bowl as the RBC layer widens. Ultimately, the RBCs will fill the entire bowl, necessitating interruption of processing to empty the bowl (see Fig. 54–4). The development of a surge technique has enabled greater purity of platelet and mononuclear cell products. This process involves blocking the flow of whole blood into the Latham bowl when an optical sensor detects the buffy coat. Then plasma from a reservoir bag is flushed rapidly into the still rotating bowl. The plasma flows through the cellular layers, thereby floating off platelets initially, followed by lymphocytes.

The plasmapheresis bowl for use with Haemonetics models V50 and PCS-2 is exclusively for collection of plasma. A cylindrical modification of the Latham bowl, it operates on the same principle.

Continuous-flow separators enable removal of components of different densities without interruption of processing. Equipment presently licensed includes apheresis separators manufactured by COBE/Gambro (Lakewood, Colo.), Fenwal (Baxter Biotech, Deerfield, Ill.), and Fresenius (Fresenius AG, Bad Hamburg, Germany).

The COBE/Gambro Spectra uses continuous-flow technology and is capable of double- or single-needle plateletpheresis (converts to intermittent flow for single-needle procedures) and double-needle leukapheresis as well as therapeutic procedures. The separation chamber is a belt-shaped channel with a lariat-like configuration to prevent twisting of the afferent and efferent lines. The system lacks a rotating seal. The plasma/buffy coat/RBC interface is automatically controlled by a microprocessor. Different software is used depending on the type of procedure (e.g., plasma exchange, granulocyte collection, or plateletpheresis). For plateletpheresis, a dual-stage channel maximizes product quality, including minimal contamination of leukocytes.

Like the COBE/Gambro Spectra, the Baxter CS3000 Plus is a seal-less system that relies on continuous-flow technology and is largely automated with numerous preprogrammed procedures. A closed system of plastic bags serves as the collection and separation chambers. Pressure plates, which are specific to the procedure being performed, affect the shape of these chambers, allowing a single tubing set to accommodate several different procedures. The addition of a novel platelet chamber, the TNX-6 separation chamber, has decreased leukocyte content of platelet products collected with this system.

Baxter's Amicus is a continuous-flow cell separator that is more portable, efficient, and operator friendly. Its novel features include ease of loading the disposable tubing kit and the unique drive mechanism for its centrifuge. The separation and collection containers resemble a belt around a spool and are uniquely configured to promote collection of small

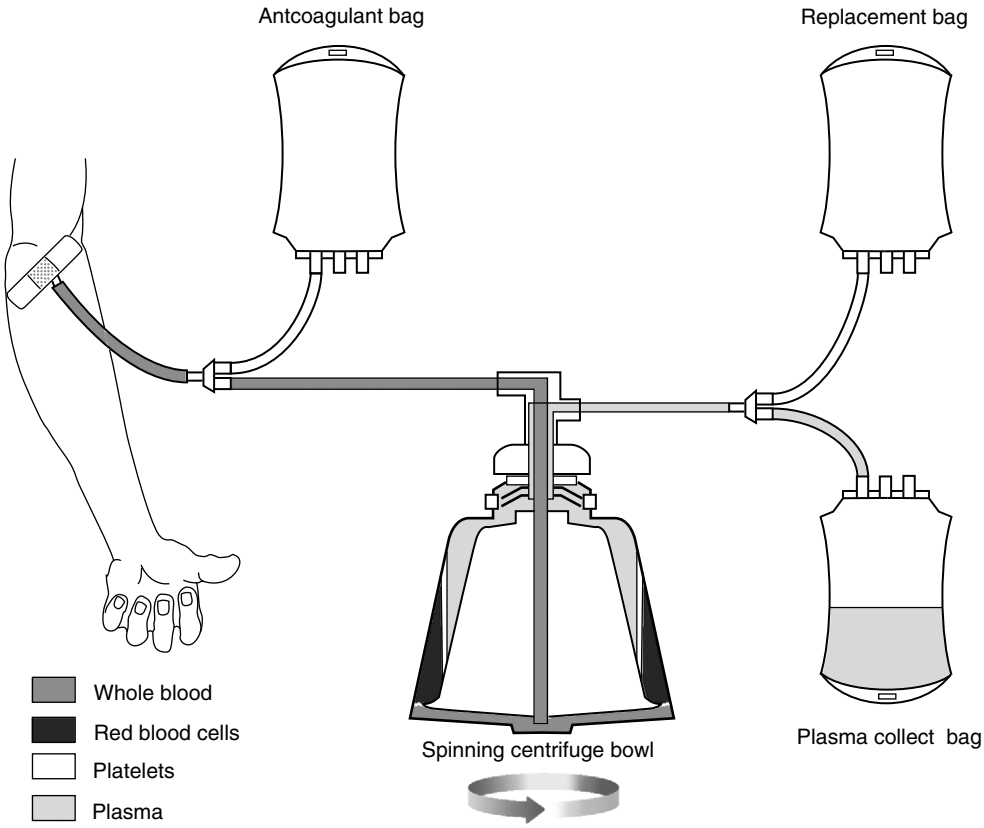

Figure 54–4 Example of an intermittent-flow apheresis procedure. Depicted is simplified representation of a plasma exchange. Whole blood enters the Latham bowl through a central channel and is dispersed at the bottom of the bowl. The blood is then forced to the periphery of the bowl and rises between two concentric conical surfaces. The centrifugal force causes the plasma, platelet-rich plasma, and red blood cells to form vertical layers. As more whole blood enters the bowl, the lighter plasma is forced up through an effluent tube and directed to the plasma collect bag. When the bowl is filled with red blood cells, the centrifuge is stopped and the pumps reversed, causing the red blood cells to be reinfused to the patient.

to large platelets, to concentrate RBCs, and to minimize mononuclear cell contamination of platelet products.

The Fresenius AS104 blood separator is another continuous-flow device using seal-less centrifugation. It offers multiple preprogrammed options as well as customized programming. For plateletpheresis, a dual-stage channel is used. A single-stage channel is used for granulocyte collections. The device also is capable of therapeutic plasmapheresis. Plasma collection as a by-product of plateletpheresis is a practical option; however, two-unit plasmapheresis collections are limited by the cost of disposable software. The AS104 does have the advantage of very low extracorporeal volume with two-needle procedures.

Filtration

Membrane-based blood separators rely on the differences in the actual size of particles rather than their density. In order of increasing size are platelets (3 μm), RBCs (7 μm), lymphocytes (10 μm), and granulocytes (13 μm). Separation of plasma from cellular elements becomes very practical because of the smaller size of instrumentation, lower extracorporeal volume, and the removal of all cellular debris, compared with centrifugal systems.

The two basic types of filtration separators are as follows: The hollow-fiber systems consist of a bundle of narrow hollow fibers with perforations along their surfaces. These are contained within a larger cylinder. As whole blood enters, the plasma will pass through the pores along the fibers, leaving a more concentrated cell suspension to exit the fibers; plasma can be collected via a side port. In the flat-plate membrane system, whole blood passes between two membranes, and plasma escapes through pores, to be collected separately from the cellular elements.

Filtration and centrifugation may be combined. Centrifugation can force plasma to separate from cellular elements via pores. Central placement of the filtration device moves the cellular elements away from the filter pores for improved efficiency. An example of this technology is the Fenwal Autopheresis-C. Originally used for plasma collection, by increasing pore size, this device can also be used to harvest platelets, although limited in efficacy. This is a discontinuous device requiring a single needle to access the donor.

Filtration techniques have been developed to attempt selective removal of a plasma constituent. If the undesirable or pathologic component is of large size, filtration of the separated plasma may afford reasonable removal. Addition of a second column with smaller pore sizes can be used. The arrangement of two or more columns in series is *cascade filtration.* Removal of low-density lipoproteins in familial hypercholesterolemia is an example of this application.[13]

Affinity Adsorption Apheresis

Affinity adsorption apheresis involves the selective extraction of immunologic or nonimmunologic substances from the circulation by means of a column, with the benefit of

returning nonextracted proteins (e.g., clotting factors) to the patient. The column contains a sorbent or ligand attached to a carrier to which patient plasma is exposed while in the extracorporeal circuit. The most commonly used column is the staphylococcus protein A column, in which staph protein A as the ligand is attached to silica as the carrier (e.g., the Prosorba column; Cypres Inc., Seattle, Wash). These columns adsorb immune complexes and immunoglobulins via their Fc portion (with greatest affinity for IgG subclasses 1, 2, and 4, and lower affinity for IgG3, IgM, and IgA).[14] The majority of patients tolerate affinity apheresis without complications, although several reports have associated significant toxicity and at least one fatality with use of the staph protein A column.[15–19] It is approved for clinical use in the United States for treatment of idiopathic thrombocytopenia purpura, and, more recently, for refractory rheumatoid arthritis.

The Adacolumn (Japan Immunoresearch Laboratories Co., Ltd, Gunma, Japan) is a new adsorptive-type extracorporeal leukapheresis device. This device comprises a single-use, direct blood perfusion–type apheresis column. This column contains cellulose acetate beads in a saline solution, which have a selective affinity for granulocytes and monocytes/macrophages. As blood passes through the column, granulocytes and monocytes/macrophages bind to the beads, but other cellular elements, such as lymphocytes, platelets, or RBCs, are not significantly adsorbed. The selective removal of granulocytes and monocytes/macrophages has demonstrated clinical improvement in patients with inflammatory bowel disease, specifically, severe active ulcerative colitis, and possibly refractory Crohn's disease.[20–23] In Japan, the Adacolumn is approved for the treatment of active ulcerative colitis, but in the United States, this device is currently in phase III trials. The Cellsorba (Asahi Medical Co., Tokyo, Japan) is another selective apheresis device that uses filtration technology to remove leukocytes for management of similar diseases.

Photopheresis

An alternative approach to immunomodulation and tumor cell therapy is the use of extracorporeal photopheresis, also known as extracorporeal photochemotherapy (ECP). Photopheresis is a leukapheresis procedure in which the buffy coat is exposed to 8-methoxypsoralen (8-MOP) and ultraviolet A (UVA) radiation and reinfused into the patient.[24–26] 8-MOP is a photoreactive agent that will irreversibly crosslink DNA when exposed to UVA radiation. 8-MOP can be entered into this system by oral ingestion (in vivo) or by instilling it into the collection bag (vide infra). Because only 10% to 15% of the body's lymphocytes are manipulated during this procedure, the immune response is not secondary to direct cytotoxicity of the 8-MOP and UVA irradiation on the abnormal T cells or tumor cells.[27] The exact mechanism evoking a clinical response is still unclear. T cells isolated from the peripheral blood after photopheresis demonstrate increased apoptosis, and macrophages and dendritic cells exhibit the ability to phagocytose these apoptotic T cells.[28] It is surmised that photopheresis enhances the immune response against pathologic proliferating T-cell clones.[29–31]

Photopheresis has been FDA approved for cutaneous T-cell lymphoma (CTCL) since 1988.[32] A typical photopheresis course consists of two procedures on consecutive days every 4 weeks.[27] Several studies have also reported on its use in the management of nonmalignant immune-related conditions such as organ transplant rejection, graft-versus-host disease (acute and chronic), and autoimmune disorders.[32,33–35]

HEMAPHERESIS "DOSE" OR GOAL

The required volume of blood to be processed to achieve a treatment goal is based on the patient's TBV, PV, or RBC volume. Because the efficacy of the collection of the component being removed decreases with increasing volumes processed (see earlier discussion), it may be necessary to process several TBVs to reach a specific therapeutic goal. Patients being treated with plasma exchange typically have one PV removed per exchange. In contrast, with cytapheresis, multiple blood volumes may have to be processed to achieve a therapeutic end point. For example, patients requiring RBC exchange for sickle cell disease or malaria may require an exchange 1 to 2.5 times TBV to reach a therapeutic goal of 90% hemoglobin A or to reduce the parasitic load to less than 5%. Similarly, leukocytoreduction, used to treat patients with hyperleukocytosis, may require the processing of 1.5 to 2 times the TBV to reduce the leukocyte count by 50%.

Extracorporeal Blood Volume Assessment and Treatment Dose Calculation

To assess the patient's ability to tolerate the extracorporeal circuit and determine the "treatment dose," the patient's TBV, RBC volume, and PV must first be calculated. In general, two methods are commonly used to calculate TBV. One approach uses gender and weight, and the second uses the additional variable of height. Although both methods overestimate the TBV in obese patients and underestimate it in very muscular patients, they do provide a reasonable approximation of the TBV (Table 54–4). The patient's RBC volume and PV are calculated based on the TBV and the patient's current hematocrit.

The total extracorporeal volume is the amount of cells and plasma that is needed to displace the saline used for priming the lines (manufacturers generally provide this volume). The RBC extracorporeal volume is the RBC volume required to fill the bowl or channel and all the tubing, which is proportional to the patient's hematocrit. The lower the hematocrit, the more whole blood must be processed before RBCs are returned to the patient. Therefore the fraction of RBCs that is extracorporeal can greatly exceed the fraction of extracorporeal "blood." For example, the total volume of the extracorporeal circuit may be 10% of the TBV, but more than 10% of the packed RBC volume may be contained in the extracorporeal circuit. The extracorporeal volume also varies depending on the system (continuous vs. intermittent flow), type of procedure, and ancillary equipment such as blood warmers or single-needle devices.

Table 54–4 Calculation of Total Blood Volume

Rule of Fives[36]	**Blood Volume (mL/kg of body weight)**			
Patient Habitus	**Obese**	**Thin**	**Normal**	**Muscular**
Male	60	65	70	75
Female	55	60	65	70
Infant/child	—	—	80/70	—
Nadler's Formula (for adults)[37]				
Male	(0.006012 × height in inches^3)/(14.6 × weight in pounds) + 604			
Female	(0.005835 × height in inches^3)/(15 × weight in pounds) + 183			

Management of Extracorporeal Volume

The general standard of care is for neither the total extracorporeal blood volume nor the extracorporeal RBC volume to exceed 15% of the patient's total blood volume or RBC volume, respectively. If the total extracorporeal volume is 15% to 20% but the extracorporeal red RBC volume is less than 15% (i.e., in a patient with a high hematocrit), a saline bolus or colloid prime may be needed to prevent hypotension secondary to intravascular hypovolemia.

If the extracorporeal total volume is less than 15% but the patient has a low hematocrit, the extracorporeal RBC volume may exceed 15%. The patient should be carefully monitored for signs of hypoxia. If the patient has a history of cardiac or pulmonary problems or is symptomatic (short of breath, tachycardic, or requiring oxygen), priming of the extracorporeal circuit with RBCs should be considered. For asymptomatic patients, both adults and children, one approach is to calculate the intraprocedure hematocrit:

Intraprocedure hematocrit =

[(Initial RBC volume–extracorporeal RBC volume)/TBV] × 100

This formula assumes that the patient is maintained in an isovolemic state during the procedure. If the intraprocedure hematocrit is equal to or greater than 24% in an asymptomatic patient, the patient typically will not require transfusion. Asymptomatic patients with chronic anemia may be able to tolerate even lower hematocrits.

CHOICE OF REPLACEMENT SOLUTIONS FOR PLASMA EXCHANGE

In the 1970s, after the introduction of cell separators for plasma exchange, it was common practice to replace plasma removed with stored allogeneic plasma. Complications with viral contamination (particularly hepatitis) and citrate toxicity led to the search for a safer alternative. Because large amounts of plasma protein that provided colloidal osmotic pressure were being removed, it seemed reasonable to replace the removed human plasma protein with human-derived plasma protein in the form of 5% albumin (which is >96% pure albumin) or plasma protein fraction (>83% pure albumin). These replacement solutions largely resolved the problems of disease transmission and citrate toxicity. Subsequently, the introduction of partial saline replacement was integrated into replacement regimens.[38,39]

In recent years, market recalls (due to Creutzfeldt-Jakob disease or bacterial contamination) and increased demand have compromised the availability of albumin and purified protein fraction. Decreased availability, increasing costs, recognition of drug interactions with albumin (i.e., angiotensin-converting enzyme [ACE] inhibitors), and a fear of disease transmission led several groups to the use of colloidal starches (hydroxethyl starches, also known as HES) as partial or full replacement for plasma during plasma exchange.[40–45] One regimen currently in use includes 3% Hespan (6% Hespan diluted 1:1 with normal saline) at 110% replacement initially, followed by a final liter of replacement with 5% albumin at 100% replacement.[43] An alternative approach used 10% pentastarch for the first half of the colloid replacement, followed by 5% albumin.[45] In some cases, 25% albumin is diluted to 5% albumin for use as replacement. Hemolysis has occurred when hypotonic solutions have been used as a diluent; 25% albumin should be diluted with normal saline.[46–48]

In specific clinical settings, patients may require replacement of a specific plasma protein (such as von Willebrand factor metalloprotease in thrombocytopenic thrombotic purpura) or clotting factors in patients at increased risk for bleeding (e.g., Goodpasture syndrome with pulmonary hemorrhage). In such cases, plasma or modified plasma (e.g., solvent/detergent-treated plasma, cryoreduced plasma supernatant) may be indicated as full or partial replacement.

Supplementation of replacement solutions (saline, colloidal starches, and albumin) with calcium can reduce the incidence of hypocalcemia secondary to citrate toxicity. In one study, the incidence of citrate toxicity was reduced from 35.6% to 8.6% with a constant calcium gluconate infusion.[49] Possible regimens include the addition of 10% calcium gluconate (10 mL per liter of return fluid) or the addition of calcium chloride ($CaCl_2$, 200 mg per liter of return fluid).[7,48] Most patients tolerate hypocalcemia without major adverse effects. However, patients with fulminant liver failure require close monitoring of ionized calcium levels to avoid severe hypocalcemia.

VASCULAR ACCESS

Apheresis procedures require high blood flow rates. Such flow rates can typically be achieved with peripheral venous access with one to two large-bore needles (16 to 18 gauge). However, the absence of peripheral access or an inability to augment venous return by fist clenching (in patients who are unconscious, confused, or uncooperative and in those who have significant muscle weakness or are easily fatigued) often necessitate the placement of central catheters.[12] Routine central catheters are flexible and are designed for positive pressure; such "soft-walled" catheters collapse under the negative pressure exerted by the cell separators during blood withdrawal. Therefore, more-rigid, specifically designed apheresis or dialysis catheters are required for apheresis procedures. Central catheters are not without risk, and much of the morbidity associated with apheresis procedures is catheter related. Catheters can be associated with infection (line or catheter sepsis), bleeding, pneumothorax or hemothorax (if placed in the chest), and air emboli. Before the placement of a central catheter, decisions must be made regarding the optimal location of the catheter for a given patient. For example, femoral catheters are relatively easy to place but are associated with increased risk of infection. Such placement may be appropriate for a patient who requires a catheter for a brief period, whereas a subclavian or tunneled catheter may be more appropriate for prolonged access.

ANTICOAGULANTS

Citrate, heparin, or a combination of citrate and heparin is used during apheresis to prevent coagulation in the extracorporeal circuit. To determine the anticoagulant of choice, the patient should be carefully evaluated for the ability to tolerate citrate versus heparin anticoagulation. Other considerations include an assessment of how the patient will tolerate an increased intravascular volume, the type and length of the procedure, the type and volume of replacement fluid, the type of vascular access, and the inlet blood flow.

Citrate prevents coagulation by binding ionized calcium, which is required for multiple steps in the coagulation cascade. A healthy liver metabolizes citrate as quickly as it is infused at typical rates. If the infusion rate exceeds hepatic metabolism, transient hypocalcemia can occur. Low calcium levels may induce mild paresthesias (perioral, distal extremities), or progress to gastrointestinal symptoms, hypotension, and, in most extreme situations, cardiac dysrhythmias or seizures. The patient in liver failure is at greatest risk. In such clinical settings, management of the patient requires frequent monitoring of ionized calcium, the possible addition of a calcium drip, a decreased citrate infusion rate, or both.

Citrate is available in three forms: ACD-A, ACD-B, and a concentrate of trisodium citrate. ACD-A is the most widely used form; it is a 3% citrate solution that may be administered at a ratio of whole blood to anticoagulant (WB/ACD ratio) of 9:1 to 14:1. ACD-B is a 2% citrate solution that is usually administered at a ratio of 6:1 or 9:1. ACD-B is used primarily with systems that have a fixed WB/ACD ratio to reduce the risk of citrate toxicity. Trisodium citrate is used with leukapheresis. Between 30 and 40 mL of trisodium citrate concentrate (46.7%) is mixed with 500 mL of a sedimenting agent (HES or Pentastarch) during leukapheresis, permitting the anticoagulant pump to titrate the sedimenting agent as well as the anticoagulant. Trisodium citrate can also be diluted with normal saline to make a solution similar to ACD. Trisodium citrate should never be administered undiluted.[50]

Heparin, unlike citrate, is not rapidly metabolized (half-life of 90 minutes) and results in systemic anticoagulation. This can be particularly problematic during plasmapheresis with nonplasma replacement (e.g., 5% albumin or hetastarch) because of the removal of plasma-associated clotting factors. Heparin may be used alone or in combination with ACD-A or ACD-B. When a combination is used, less heparin and a lower volume of ACD-A are required for effective anticoagulation. Such combinations therefore decrease the incidence of citrate toxicity, minimize the systemic anticoagulation caused by heparin alone, and reduce the total fluid volume of the procedure. Use of heparin alone may result in platelet aggregation during cytapheresis procedures.

DRUG CLEARANCE

On rare occasions, plasma exchange is used to assist in the treatment of acute drug toxicity when other modalities such as gastric lavage, dialysis, hemoperfusion, and forced diuresis have been ineffective. Drugs that are lipophilic and highly protein bound, with long half-lives and small volumes of distribution, are most effectively removed. Plasma exchange has been used to improve drug clearance with barbiturates, theophylline, vincristine, cisplatin, digoxin antidigoxin-antibody complexes (in the presence of renal failure), paraquat, quinidine, tricyclic antidepressants, acetaminophen, and phenytoin.

More commonly, one encounters the question of the effect of plasma exchange on therapeutic drug dosing. In general, drugs that are most affected have a small volume of distribution and are extensively protein bound (similar to drugs that are treated with plasma exchange in acute toxicity). Drug kinetics in the context of plasma exchange has not been extensively studied. The limited data suggest that supplemental dosing of prednisone, digoxin, cyclosporine, ceftriaxone, ceftazidime, valproic acid, and phenobarbital after plasma exchange is not necessary.[51,52] In contrast, dosing of certain drugs such as salicylates and tobramycin should be supplemented, and phenytoin, in which there are conflicting reports of clearance, requires careful patient monitoring. In general, removal of a drug is likely to be increased during the distribution phase after administration. Therefore, it would seem prudent that when possible, drug doses should be administered after a plasma exchange and not immediately before the exchange.

EFFECT ON CLOTTING AFTER PLASMA EXCHANGE

Therapeutic plasma exchange is generally associated with the rapid (and repeated) removal of large quantities of plasma and its associated coagulant proteins.[9,42,43,53–55] When coagulant protein–deficient replacement fluids such as albumin, saline, and colloidal starches are used, an acute decrease in clotting factor activity, varying from 40% to 70% of baseline, can be observed immediately after the exchange. This is usually associated with a small prolongation in measured prothrombin time (PT) and activated partial thromboplastin time (aPTT), although such values frequently remain within the normal range. Fibrinogen, having a volume of distribution that is almost exclusively intravascular, is the clotting factor most depleted. Levels of clotting factors usually return to normal within 1 to 2 days after an exchange. The consensus is that, in the absence of an underlying hemostatic defect or liver disease, use of clotting factor–free replacement solutions is appropriate.

An unintentional consequence of plasma removal is a reduction in circulating platelets. Mean reduction of platelets after a plasma exchange has been variably reported to range from 9.4% to 52.6%.[7,43,56–58] This wide range probably reflects differences in the amount of PV processed, the cell separators used, and the settings used. Larger volumes processed and low-speed settings (decreased centrifugal force) are associated with greater platelet loss.[59] Despite mean decreases in platelet counts of 52.6% after 1.6 PVs exchanged, Sultan and colleagues[53] found that the platelets (as well as all clotting factors measured, with the exception of antithrombin [AT III]) had almost reached or even exceeded their initial values after 48 to 96 hours (just before the next plasma exchange). We have also observed normal platelet counts 48 hours after 1 PV (just before the next plasma exchange).

In a hemostatically compromised patient or if large-volume daily exchanges are performed, hemostatic parameters should be monitored, and the replacement supplemented with plasma or platelets, as clinically indicated.

ADVERSE REACTIONS

Adverse reactions associated with therapeutic apheresis are uncommon. A 1995 survey conducted by the American Association of Blood Banks Hemapheresis Committee involving 18 centers and 3429 procedures, reported 242 adverse invents involving 163 procedures (4.75% of all procedures, 6.87% of first-time procedures, and 4.28% of repeated procedures).[8] Mild reactions were not reported in this study. The types of reactions reported were as follows: transfusion reactions, 1.6%; citrate-related nausea and

vomiting, 1.2%; hypotension, 1.0%; vasovagal nausea and vomiting, 0.5%; diaphoresis, 0.5%; tachycardia, 0.4%; respiratory distress, 0.3%; tetany or seizure, 0.2% (associated with fresh frozen plasma replacement); and chills or rigors, 0.2%. Three deaths, attributed to primary disease, were reported in this study. Although deaths have occurred in patients being treated with therapeutic apheresis, most have occurred in critically ill patients and were not thought to be secondary to the apheresis procedures. Mortality rates are largely a function of the patient population treated. For example, estimates of the mortality of patients with thrombotic thrombocytopenia purpura range from 10% to 20%.[60,61] Overall, estimated mortality rates of 1 per 1000 to 3 per 10,000 procedures more accurately reflect the underlying disease of the patient than the risk of the procedure.[8,62]

Adverse reactions or complications that occur in the setting of therapeutic apheresis may be caused by the procedure (anticoagulant, replacement fluids), by an underlying condition (anemia; renal, cardiac, hepatic disease; sepsis; dehydration), or adjunctive therapy (vasopressors, antihypertensives, diuretics). Before therapy is initiated, the patient should be carefully evaluated for risk factors, and a care plan should be developed to minimize risk.

Although the following reactions may occur outside the setting of apheresis, the use of citrate anticoagulation, the large volume, and the rapid infusion of a variety of replacement solutions predispose the apheresis subject to the following adverse events. Mild hypocalcemia or citrate reaction (characterized by tingling, oral paresthesias, or chest discomfort) is the most commonly encountered adverse reaction. Such reactions are usually mild and easily managed by slowing the infusion rate, changing the WB/ACD ratio, or giving oral calcium. More severe reactions may be treated or prevented by administering intravenous calcium. Calcium chloride may be added to the replacement fluid (200 mg per liter of 5% albumin or 3% to 6% HES) or given at a very slow rate intravenously (200 mg, diluted to ≥20 mg/mL, infused over 2 minutes) when replacing with fresh frozen plasma.

Allergic-type reactions, ranging from mild urticaria to anaphylaxis, are associated with the use of replacement fluids, including plasma, HES, and albumin. Premedication with antihistamines may prevent allergic reactions in most patients, but some patients develop mild to severe reactions even with premedication. In this group of patients, multiple strategies may be required. In addition to premedication with antihistamines such as histamine$_1$ antagonists (e.g., diphenhydramine), use of a histamine$_2$ blocker (e.g., hydroxyzine, cimetidine), and a continuous antihistamine drip may be effective in preventing breakthrough reactions.

Atypical allergic or anaphylactoid reactions have been described, respectively, with ethylene oxide gas sterilization of tubing sets and with drug interactions between ACE inhibitors and albumin. Ethylene oxide reactions are usually characterized by periorbital edema with chemosis and tearing.[63] Double priming of the tubing is useful in the prevention of the recurrence of such a reaction. ACE inhibitor reactions are associated with albumin infusion during therapeutic plasma exchange.[40] It is thought that the symptoms are caused by rapid infusion of low levels of prekallikrein activator (a metabolite of clotting factor XII) found in the albumin product, which activates prekallikrein to bradykinin, a naturally occurring vasoactive peptide. Metabolism of bradykinin is inhibited by the ACE inhibitor, leading to an accumulation of bradykinin. The patient may experience mild to severe facial flushing, hypotension, and a feeling of doom. ACE inhibitor therapy should be discontinued 24 to 48 hours before the start of therapeutic plasma exchange (TPE). If the patient's condition is such that the procedure cannot be delayed for 24 to 48 hours, a colloidal starch such as HES may be used for replacement.

CONCLUSION

The field of apheresis continues to evolve in both the technology and the understanding of how we can affect the pathophysiology of disease with apheresis. Careful assessment of the patient and expertise in therapeutic apheresis is essential to optimize therapy and minimize adverse consequences. Subsequent chapters explore in depth the use of therapeutic apheresis for both cellular and plasma therapy.

Chapter 55

Therapeutic Plasma Exchange

Bruce C. McLeod

Like many true stories, the history of therapeutic plasma exchange (TPE) is sprinkled with serendipity. TPE arose from the ideas and efforts of a number of people who had no intention of treating patients and was helped along by others who were not interested in a device for exchanging plasma. After a long period of inadvertent stage setting, TPE emerged over a fairly short interval as a credible therapy and has become an important treatment for a number of diseases.

Seminal credit is usually given to Abel and colleagues,[1] who, in pursuing higher yields of antisera for serotherapy, devised manual plasmapheresis in 1914 to obtain more plasma from immunized horses without exsanguinating them. Skoog and Adams[2] and Schwab and Fahey[3] later applied this technique to patients with the hyperviscosity syndrome. Recognition should also be extended to Dr. Edwin Cohn and his associates[4] (especially his engineering consultant, Alan Latham[5]), who, in the 1950s, adapted for blood-component donation the concept of continuous-flow centrifugation invented 60-odd years earlier for the dairy industry by Carl Gustav Patrick De Laval.[6] Nor should one forget to mention Dr. Emil Freireich, George Judson, and others at the National Cancer Institute, who, in the 1960s, constructed a centrifugal blood cell separator to remove white blood cells from patients with chronic myelogenous leukemia.[7] Further refinement of concepts originating with these workers led eventually to the commercial availability of several semiautomated blood-separator instruments for clinical use.

RATIONALE FOR THERAPEUTIC PLASMA EXCHANGE

In the 1960s and early 1970s, the notion of treating a patient with a large-scale plasma exchange carried out with such an instrument began to take hold, first in Rh-sensitized women[8–10] and patients with systemic lupus erythematosus (SLE)[11,12] and then in other illnesses. The common threads linking these disorders were the beliefs that a circulating macromolecule was a crucial pathogenetic factor and that meaningful clinical improvement could be brought about by removing the material.

TPE has often been likened to the practice of bloodletting to remove evil humors. The notion of therapeutic removal is a sound one that has changed little since medieval times; however, the concept of an evil humor has been refined. Three subtypes of molecules are candidates for therapeutic removal: (1) molecules that are troublesome because of their binding specificity: these are always antibodies and usually autoantibodies; (2) molecules that confer troublesome physical properties on the plasma and hence on the blood, such as hyperviscosity or cold insolubility: these are also usually antibodies, although they are often in immune complexes; and (3) molecules that have a nonimmune toxicity, such as low-density lipoproteins (LDLs). An important therapeutic effect arising from removal is more easily envisioned for large molecules having a relatively long half-life in the circulation and a corresponding low synthetic rate. The majority of successfully treated disorders are due to pathogenic immunoglobulin G (IgG), which has these properties. It has been hypothesized at various times that removal of complement or coagulation proteins, or both, or mediators of inflammation derived from them or secreted by inflammatory cells might contribute to a therapeutic effect. Such mechanisms are unlikely to be of clinical importance because the candidate molecules have relatively short half-lives or rapid synthetic rates, and no such effect has been proven.

TPE can also be used in a fourth way, not foreseen by medieval barbers or 19th-century physicians, and that is to achieve relatively high levels of a normal plasma constituent that is not available in a concentrated form. These four distinct rationales for TPE are summarized in Table 55–1.

GENERAL PRINCIPLES OF THERAPEUTIC PLASMA EXCHANGE

Mathematical Principles

Patients sometimes liken TPE to an oil change, and it is instructive to consider why this analogy is misleading. A 5-L oil exchange that is nearly 100% efficient can be performed on an automobile engine in 10 minutes because the engine is not running during the exchange. By contrast, limitations are imposed on the rate and efficiency of TPE by the need to keep the heart pumping and the blood stream nearly full throughout the procedure. These requirements dictate that only a small proportion of the total blood volume be extracorporeal at any given moment. TPE must therefore proceed gradually, either continuously or in small increments.

Consequently, as an exchange progresses, an increasing proportion of the material removed is not the patient's plasma but replacement fluid infused earlier in the procedure. In such a process, the behavior of an entirely intravascular substance that is absent in the replacement medium is described by the formula

$$y_x = y_0 e^{-x}$$

where y_0 is the starting concentration of the substance, e is the base natural logarithm, and y_x is the concentration of the substance after x patient plasma volumes have been

Table 55–1 Rationales for Therapeutic Plasma Exchange

Goal of TPE Therapy	Example
Remove antibody with harmful specificity	Autoantibody
Remove protein (usually antibody) with harmful physical property	Hyperviscosity
Remove nonantibody toxin	Low-density lipoprotein
Correct deficiency of plasma factor	Thrombotic thrombocytopenic purpura

exchanged. If y_0 is assigned a normalized value of 1.0, a plot of the function yields the smooth asymptotic middle curve in Figure 55–1, which describes a continuous exchange. The flanking curves, which describe small incremental discontinuous exchanges, are similar.[13] Experimental work has shown that this formula is also predictive of exchange outcomes for macromolecules such as LDL[14] and IgG[15] that have a substantial extravascular reservoir, if equilibration between the intravascular and extravascular compartments is slow relative to the rate of removal.

As noted earlier, the molecule targeted for removal in many patients is an IgG antibody. Because slightly more than half of IgG is extravascular[13] and removal of intravascular IgG becomes progressively less efficient with larger exchange volumes, most practitioners choose to limit an exchange to 1 to 1.5 patient plasma volumes, which removes 60% to 75% of intravascular material and limits side effects associated with depletion of normal plasma components.

Equilibration with extravascular sources over 1 to 2 days increases the intravascular IgG level, and further removal by exchange can then be undertaken more advantageously. The effects of a series of TPEs on intravascular, extravascular, and total IgG are shown schematically in Figure 55–2. For reasons given subsequently, human serum albumin is the most common replacement fluid in TPE. In these cases, all plasma constituents except albumin are removed but not replaced, and removal in an individual exchange is almost completely nonselective.[15] However, because most other plasma constituents are resynthesized much more rapidly than IgG, a series of such exchanges results in fairly selective lowering of IgG levels over a course of exchanges,[16] as shown in Figure 55–3.

Regulation of IgG Metabolism

Because reduction of IgG levels is a frequent goal of TPE, it is worthwhile to consider certain details of IgG metabolism. The catabolic rates for IgG1, IgG2, and IgG4, which constitute about 90% of total IgG, are proportional to total IgG level. Accordingly, their half-lives are inversely proportional to concentration.[17–20] This observation has long been attributed to the existence of a saturable receptor that protects IgG from catabolic pathways.[21] This receptor has been characterized and shown to be identical to the FcRn receptor in neonatal intestinal epithelium.[22]

Synthetic rates for IgG are difficult to measure in humans. Certain animal experiments concerning levels of specific antibody fostered the belief that the synthetic rate for IgG is variable and exhibits negative feedback, such that synthesis increases when IgG or specific antibody levels, or both, are lower.[23] By contrast, Junghans[24] has shown that knockout mice genetically deficient for the FcRn receptor, which rapidly catabolize IgG, have the same IgG synthetic rate as normal mice despite maintaining very low IgG levels. This observation argues against any feedback regulation of IgG synthesis and suggests that the generalized hypogammaglobulinemia induced by TPE would not produce any rebound increase in IgG synthesis.

Intravenous immunoglobulin (IVIG) therapy has been reported effective in a number of antibody-mediated diseases

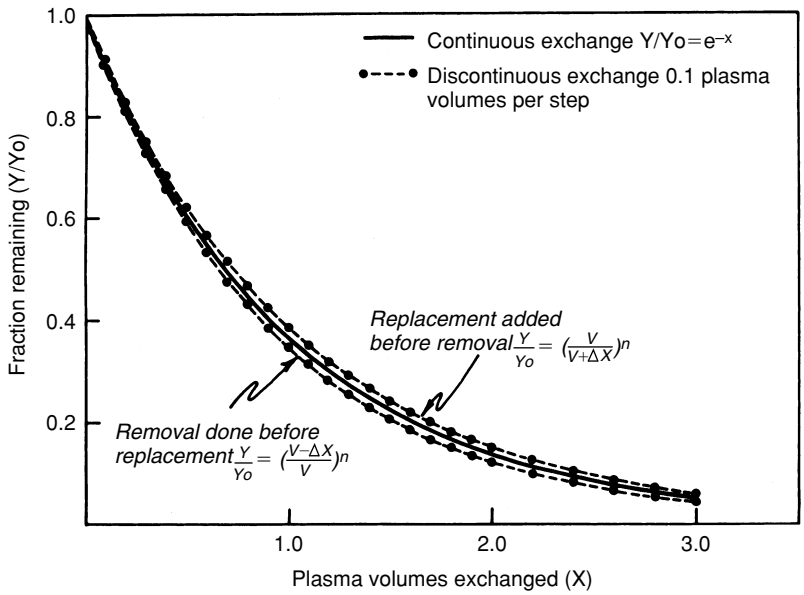

Figure 55–1 Calculated fraction of intravascular substance remaining during a plasma exchange, assuming no equilibration with extravascular material. (From Chopek M, McCullough J. Protein and biochemical changes during plasma exchange. In Berkman EM, Umlas J [eds]. Therapeutic Hemapheresis. Washington, D.C., American Association of Blood Banks, 1980, p 17.)

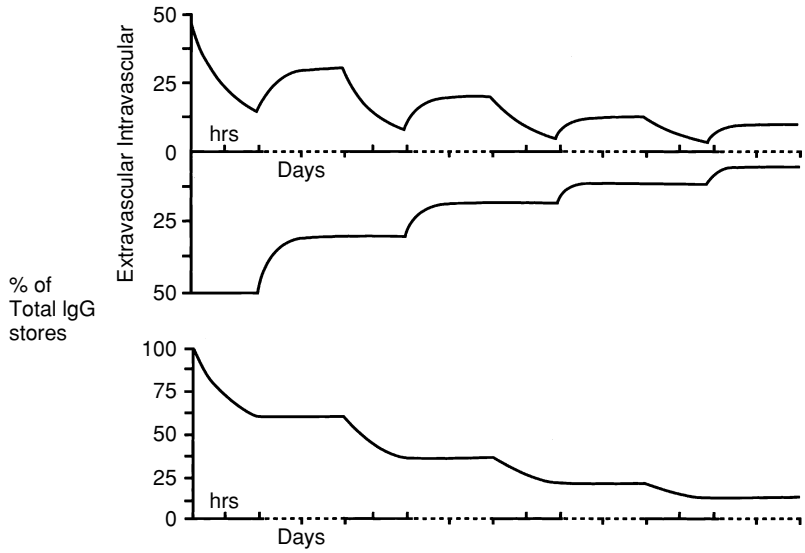

Figure 55–2 Computer-generated curve estimating amounts of intravascular and extravascular immunoglobulin G (IgG) (upper curves) and total immunoglobulin G (IgG; lower curve) during a course of four 1-plasma-volume therapeutic plasma exchanges with an IgG-free replacement medium. Published formulas were used for rates of removal during exchanges and reequilibration after exchanges.[13] No correction was made for continuing synthesis.

in which TPE has also been used. Yu and Lennon[25] have proposed that the beneficial action of IVIG is to compete with endogenous IgG antibodies for FcRn receptors and thereby promote increased catabolism of the latter, including pathogenic antibodies. In this view, the therapeutic effects of IVIG and TPE are essentially the same; that is, both lower harmful autoantibody levels. TPE lowers levels quickly but may be followed by slower catabolism, whereas IVIG presumably has a slower onset of action but promotes rapid catabolism.

Replacement Fluids

Saline replacement alone can suffice when only 500 to 1000 mL of plasma is removed in a manual plasmapheresis, but colloid must be given in a multiliter plasma exchange. Available colloid replacement fluids are listed in Table 55–2, which also summarizes their relative advantages and disadvantages. The standard replacement medium for most indications is 5% human serum albumin in normal saline; however, substitution of 25% to 50% of the volume removed with saline is well tolerated in certain groups of patients.[16,26] Although it is a pooled product, albumin is considered preferable to plasma as a source of replacement colloid because (1) it can be pasteurized under conditions that inactivate known blood-borne infectious agents, (2) it can be given without regard to blood type, and (3) it does not require thawing or other preparation before use. Adverse reactions to albumin are infrequent.[27] Albumin exchanges produce temporary deficiencies of other plasma proteins, such as coagulation factors; however, these are usually subclinical and are rapidly corrected by reequilibration and resynthesis.[15,28]

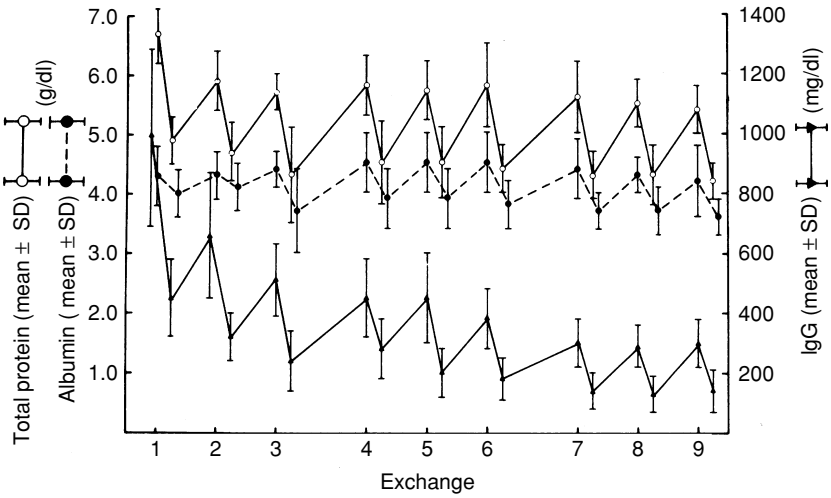

Figure 55–3 Total protein, albumin, and immunoglobulin G (IgG) levels before and after therapeutic plasma exchange with albumin/saline replacement. Exchanges were carried out 3 times per week for 3 weeks on seven patients. Points and ranges represent means and standard deviations. Note the disproportionate decrease in IgG levels. (From McLeod BC, Sassetti RJ, Stefoski D, Davis FA. Partial plasma protein replacement in therapeutic plasma exchange. J Clin Apheresis 1983;1:117.)

Table 55–2 **Colloid Replacement Fluids for Therapeutic Plasma Exchange**

Fluid	Advantages	Disadvantages
5% Albumin	Viral safety Convenience Reactions rare	High cost Most proteins not replaced
Single-donor plasma*	All proteins replaced	High cost Inconvenient† Citrate reactions Urticaria Infection possible
6% Hetastarch	Low cost Viral safety Convenience	No proteins replaced Hypotensive reactions Dosage limit Slow catabolism

*Fresh frozen plasma or cryoprecipitate-poor plasma.
†Must be thawed before use; must match patient's ABO type.

A meta-analysis published in 1998 suggested that critically ill patients resuscitated with albumin had a somewhat higher mortality than did those resuscitated exclusively with crystalloid.[29] A subsequent meta-analysis that included more patients did not confirm this finding,[30] and a recent prospectively randomized study comparing albumin with saline for fluid resuscitation in all patients admitted to intensive care units showed no survival disadvantage for albumin recipients.[31] Although further developments in this area will bear watching, no trend toward increased mortality has been apparent in decades of albumin use in TPE.

In a few circumstances, replacement with donor plasma is deemed preferable. Prominent among these is the treatment of thrombotic microangiopathies.[32] Affected patients are customarily exchanged with fresh frozen plasma (FFP) or cryoprecipitate-poor plasma because of abundant evidence that thrombotic thrombocytopenic purpura (TTP) responds better to plasma than to albumin. In addition, plasma is often given to patients with preexisting thrombocytopenia or humoral coagulopathy, who may have bleeding complications when the dilutional coagulopathy of an albumin exchange is superimposed. Use of plasma is associated with a higher incidence of immediate adverse effects, however, most notably urticarial and hypocalcemic reactions.[33]

One group has tried infusing a solution of hydroxyethyl starch (HES), a less costly volume expander, in the early part of an exchange. They reasoned that recommended dosage limitations for HES would not actually be exceeded because much of the infused HES would be removed in exchange for albumin infused later. This group has reported successes, albeit with a higher incidence of side effects.[34]

Selective Extraction of Plasma Components

Practitioners of TPE have long recognized the apparent wastefulness inherent in removing and discarding *all* plasma components in an effort to deplete just *one*. The concept of selective extraction of the pathogenic component from separated plasma, with recovery and reinfusion of the rest, was recognized early as an attractive goal. Experience with off-line separation of cryoglobulins[35] provided early evidence of practicality and efficacy; however, although a number of methods and applications for on-line separation have been explored,[36] commercial availability and widespread acceptance have been slow to be realized.

Prominent obstacles to commercially practical devices have included the high cost and limited capacity of sorbents that are biocompatible and truly selective, and the high extracorporeal volume associated with on-line sorbent modules that have a depletion capacity equivalent to that of TPE. In the past decade, several devices have become available that use pairs of small, low-capacity sorbent modules. Flow cycles are alternated, with one module absorbing material from patient's plasma, while the absorbent capacity of the other is regenerated by elution. This approach to selective extraction requires an additional instrument to manage the cycling-elution-regeneration process. A semiselective system of this type uses staphylococcal protein A to deplete IgG.[37] Other devices extract LDL selectively from the plasma of patients with familial hypercholesterolemia.[38,39]

Indication Categories

Subsequent sections of this chapter deal with specific indications for TPE. To help practitioners assess the potential utility of apheresis therapy in specific circumstances, two organizations, the American Society for Apheresis (ASFA) and AABB, have described indication categories for therapeutic apheresis.[40,41] The definitions used by the two organizations are similar and can be summarized as follows. Category I denotes diseases for which apheresis therapy is a standard and acceptable first-line therapy, although not always mandatory. Category II includes diseases in which it is a valuable second-line therapy, to be offered when first-line measures are contraindicated, fail, or are poorly tolerated. Category III indicates either uncertainty related to a paucity of data or controversy because of conflicting reports. Category IV implies negative data from controlled trials or anecdotal reports. The indication categories assigned by both organizations are given in tabular form for the diseases in each of the following sections.

THERAPEUTIC PLASMA EXCHANGE IN NEUROLOGIC DISORDERS

Immune processes, especially those that produce circulating antibody to structures in the nervous system, have been implicated in a number of neurologic diseases, and TPE has become an important therapeutic modality for many of them.[42] The diseases to be considered in this section are listed in Table 55–3, along with the indication categories assigned them by ASFA and AABB.[40,41]

Guillain-Barré Syndrome

Guillain-Barré syndrome (GBS) is a disease of the peripheral nervous system. It is the most common cause of acute paralysis with areflexia in the Western world, having an incidence of 1 to 2 cases per 100,000 population per year. It typically begins with symmetrical distal paresthesias, followed by leg and arm weakness. Symptoms progress proximally and reach a nadir by 14 to 30 days after onset. About one fourth of those affected have a mild illness and remain ambulatory throughout. The remaining patients are disabled by more serious paralysis and may have oropharyngeal and respiratory weakness as well. About one fourth require ventilatory

Table 55–3 **ASFA/AABB Indication Categories for Therapeutic Plasma Exchange in Neurologic Disorders**

Disorder	Indication Category*
Guillain-Barré syndrome	I
Chronic inflammatory demyelinating polyneuropathy	I
Peripheral neuropathy with monoclonal gammopathy	I/II
Myasthenia gravis	I
Lambert-Eaton myasthenic syndrome	II
Paraneoplastic neurologic syndromes	III
Stiff-person syndrome	III
Rasmussen encephalitis	III
Sydenham chorea	II
PANDAS	III
Multiple sclerosis	III

*I, standard first-line therapy; II, second-line therapy; III, controversial; IV, no efficacy.

PANDAS, pediatric autoimmune neuropsychiatric disorders associated with streptococcal infection.

assistance at some point, and the worst cases are marked by quadriplegia, ophthalmoplegia, and prolonged ventilator dependence. Variant presentations—with arm weakness predominating, with axonal degeneration instead of demyelination, or with symptoms limited to ophthalmoplegia, ataxia, and areflexia (Fisher syndrome)—are also possible. Spinal tap usually reveals few cells and only a moderately elevated protein concentration. A conduction block indicative of demyelination is usually found in electrophysiological studies, although inexcitability may be seen in the axonal form of GBS.[43–45]

Several lines of evidence suggest that the demyelination observed histopathologically is due to circulating antineuronal antibodies. Early experiments showed that sera from GBS patients produced demyelination in experimental animals.[46,47] Other studies have identified a variety of antimyelin antibodies in the sera of many patients with GBS.[48–50] A clinical association of GBS is found with a history of recent infection.[43] An association with *Campylobacter jejuni* infection[51–53] is especially strong, and studies have suggested a specific link to the Penner strain 19 of *C. jejuni* in 30% to 40% of GBS cases,[54] with antibodies formed to a strain-specific lipopolysaccharide that may be antigenically similar to the myelin ganglioside GM1.[55] Epidemic Chinese acute motor neuropathy, an illness of rural Chinese children, is clinically similar to GBS and is also associated with *C. jejuni* infection and anti-GM1 antibodies.[56] A number of other infectious agents, including cytomegalovirus, Epstein-Barr virus, *Mycoplasma pneumoniae,* and *Hemophilus influenzae* have also been associated with GBS.[57]

Spontaneous recovery is the rule in GBS and is perhaps associated with the decline in antibody levels expected after recovery from infection. Patients with mild illness require no therapy, but more severely affected patients need careful observation so that appropriate intervention with supportive therapies, such as mechanical ventilation, can be accomplished in a timely fashion.[43–45] Neither oral nor pulse intravenous steroids are beneficial in GBS.[58] Several small series and case reports suggested that TPE could favorably alter the course of the disease.[59–63] This evidence of benefit was confirmed by sizable randomized controlled trials that documented its effectiveness in shortening recovery time and reducing disability.[64–69]

The North American trial enrolled 245 disabled patients, 142 of whom received TPE.[66] At 4 weeks after entry, 59% of the treated patients had improved one clinical grade versus 39% of control subjects, with the mean improvements being 1.1 and 0.4 grades, respectively. The median time to improve one grade was only 19 days in treated patients versus 40 days in control patients, and median times to walk unassisted were 53 and 85 days, respectively. For ventilated patients, the median times to weaning were 24 and 48 days, respectively, and the median times to walk unassisted were 97 and 169 days. Similar hastening of recovery in severely affected patients was shown in the trial by the French Cooperative Group involving 220 patients.[67] In another study that enrolled 556 patients, the French group showed that benefit from TPE accrued even to mildly affected patients.[68] The typical treatment schedule in these trials included five or six exchanges of 1 to 1.5 plasma volumes over 7 to 14 days. Albumin replacement and FFP were specifically compared in the French trial. FFP caused more side effects[70] but offered no therapeutic advantage.[67] GBS patients may need careful monitoring, perhaps in an intensive care unit, because they may have autonomic neuropathy and are more likely to experience hemodynamic instability during TPE.[71]

Later evidence suggested that IVIG also is beneficial in GBS.[72] A large multi-institutional trial compared IVIG, TPE, and TPE followed by IVIG, with 121 to 130 patients in each treatment group.[73] The mean disability-grade improvements at 4 weeks were 0.8, 0.9, and 1.1, respectively, and the median times to walk unassisted were 51, 49, and 40 days, respectively. Although the trends favored TPE plus IVIG, none of the differences was statistically significant. TPE and IVIG are considered equivalent recommended therapies for GBS by the Quality Standards Subcommittee of the American Academy of Neurology.[74]

Chronic Inflammatory Demyelinating Polyneuropathy

Chronic inflammatory demyelinating polyneuropathy (CIDP) is an acquired neuropathy that has either a continuously progressive or an intermittent, relapsing course. Both sensory loss and weakness are typically present, with both proximal and distal sites usually affected. Proximal weakness helps to distinguish CIDP from other chronic neuropathies, and progression for more than 2 months differentiates it from GBS. Nerve-conduction studies should reveal evidence of demyelination, as should nerve biopsies. Nerve-root biopsies may show patchy inflammatory infiltrates. The cerebrospinal fluid protein is moderately elevated, but the cell count is usually less than 10 per microliter. Diagnostic criteria prepared by the American Academy of Neurology require lumbar puncture and nerve biopsy for a definitive diagnosis of CIDP; however, other diagnostic schemes require these tests only when clinical and/or nerve-conduction findings are inconclusive. Treatment is recommended for all CIDP patients, and responsiveness to treatment is expected in 60% to 80%. CIDP may be idiopathic or may arise in the context of an associated disease, such as inflammatory bowel disease, chronic active hepatitis, connective tissue disease, Hodgkin's disease, human immunodeficiency virus (HIV) infection, or monoclonal gammopathy.[75–77]

The etiology of CIDP remains unclear; however, the disease associations, the similarities to GBS, and the histopathology all support an immune process. The fact that some cases are associated with a monoclonal protein suggests an antibody-mediated disorder, as do the findings that experimental allergic neuritis, an animal model of CIDP, can be transferred with serum[78] and that antimyelin IgG from patient sera can cause electrophysiologic and pathologic features of CIDP in animals.[79] Later studies have shown antibody to myelin components such as GM1,[80] P_0 and P_2 proteins,[81] and β-tubulin[82] in the sera of patients with CIDP, although no cause-and-effect relation has been established. Abnormalities of cell-mediated immunity have also been identified.[77]

Most patients with CIDP respond to corticosteroids in moderately high doses. Standard therapy consists of a course of prednisone at perhaps 100 mg/day for an adult, followed by gradual tapering to alternate-day therapy when a functional plateau is reached.[75] The successful application of TPE in GBS, along with evidence for a circulating factor in CIDP, provided the rationale for early trials of TPE in CIDP patients who had not responded to steroids or were unable to tolerate them. A double-blind, sham-controlled crossover trial of 3 weeks of TPE reported by Dyck and colleagues[83] in 1986 showed improvement in 5 of 15 treated patients, with a similar proportion responding after crossover in the group randomly assigned to sham. Many patients worsened after TPE was stopped, however. A similar study was reported by Hahn and coworkers[84] in 1996 with 18 previously untreated patients. Twelve of 15 patients who completed the trial improved during the TPE portion. Improvement began after a shorter delay than is usually seen with steroid therapy, and its rate was more rapid. These patients were given prednisone for 6 months after completing TPE, and many maintained good function after recovery from a brief relapse when TPE was stopped.

An effect of IVIG on CIDP has also been sought.[85] Early controlled trials comparing IVIG with a control infusion of albumin were not conclusive but suggested a superior effect for IVIG.[86–89] Hahn and colleagues[90] published a double-blind, placebo-controlled trial with crossover in 30 patients. Study patients were permitted to take low stable doses of prednisone. Overall, 19 patients, or 63%, responded to IVIG, and 5 (17%) responded to placebo. Hughes and colleagues.[91] reported a randomized crossover trial in 32 patients comparing 6 weeks of oral prednisone with IVIG, 1.0 g/kg on 2 consecutive days. The responses were similar, supporting efficacy for IVIG. Two studies comparing IVIG with TPE in CIDP have been published. In an uncontrolled retrospective study by Choudhary and Hughes,[92] 21 (64%) of 33 patients had major improvement after TPE treatment while, at the same institution, 14 (67%) of 21 patients responded to IVIG. In a prospective observer-blinded crossover study of 20 patients at the Mayo Clinic, both therapies were adjudged to produce rapid and statistically significant improvement, and the authors concluded that either therapy was appropriate as a primary treatment.[93] TPE protocols in the preceding studies have tended to specify relatively long courses of treatment. A proposed schedule is three 1 plasma volume exchanges per week for 2 weeks, followed by two exchanges per week for another 4 weeks.[76]

Peripheral Neuropathy and Monoclonal Gammopathy

About 10% of patients with polyneuropathy have a circulating monoclonal immunoglobulin. The background incidence of such proteins is only 1% in adults older than 50 and increases to only 3% in adults older than 70.[94,95] Thus, the epidemiology suggests a causal relation. This idea has been strengthened by studies showing that antimyelin antibody activity is expressed by the monoclonal proteins of many patients with neuropathy. Antibody to a carbohydrate epitope on myelin-associated glycoprotein (MAG) is found in a majority of IgM-associated neuropathies.[96] The same epitope occurs in myelin glycoprotein P_0 and on other gangliosides in nerve cell membranes.[97,98] Anti-MAG injection is known to produce demyelination in experimental animals.[99] Other patients have antibodies to myelin sheath sulfatides, to membrane-associated chondroitin sulfate C moieties, or to the GM1 ganglioside.[97,98]

Clinical features of monoclonal gammopathy–associated neuropathy are mostly similar to those of CIDP[76]; however, sensory features tend to be more prominent, and although progression tends to be slower, it is also more relentless, and spontaneous improvement is uncommon.[100,101] Neuropathy is more prevalent in patients with IgM paraproteins than in those with IgG or IgA[102] except in osteosclerotic myeloma, in which the prevalence of neuropathy with IgG or IgA proteins is quite high, sometimes as a part of the POEMS syndrome (polyneuropathy, organomegaly, endocrinopathy, monoclonal protein, skin changes).[103] Nerve biopsies show demyelination, axonal degeneration, and fiber loss, and immunofluorescence may demonstrate IgM and complement in IgM-associated cases.[95]

Patients with B-cell malignancies such as myeloma or Waldenström macroglobulinemia should be treated with chemotherapy protocols appropriate for their diagnosis and may experience improvement in the neuropathy. Many patients have neuropathy in the context of a monoclonal gammopathy of undetermined significance (MGUS) and are treated with immunosuppressive regimens similar to those used in CIDP.[95]

TPE has been shown to be effective in MGUS-associated neuropathy. In a sham-controlled trial in 39 patients, twice-weekly exchange led to improvement in disability scores, weakness scores, and electrodiagnostic parameters in the blinded portion of the trial. Similar improvement occurred subsequently in sham-treated patients who received true TPE in an open follow-up.[104] Response was more frequent in patients with IgG and IgA paraproteins than in those with IgM. This trend was also noted in other studies.[105–107]

Myasthenia Gravis

Myasthenia gravis (MG) is a disease of the neuromuscular junction characterized by weakness or undue fatigability, or both, in skeletal muscle. Ocular myasthenia, with diplopia and ptosis, is a frequent presentation, but other muscles are eventually affected in most patients. Involvement of muscles innervated by other cranial nerves leads to the most serious symptoms, including inability to swallow secretions and respiratory insufficiency.[108,109]

Most patients with myasthenia have circulating antibodies to a portion of the α-subunit of the acetylcholine receptor molecule (AChR) on the muscle cell motor end plate.[108–110] At least three mechanisms exist by which such antibodies can cause weakness:

1. They can block receptors competitively so that acetylcholine released from the nerve ending cannot gain access.

2. They can increase turnover of receptors in a manner that requires crosslinking and leads to a decreased number of receptors available to receive signals.
3. They can mediate target-cell damage by complement or inflammatory cell attack, or both.[111]

The third mechanism probably leads to the most common histopathologic findings, which are simplification of the normally convoluted junctional folds that bear the receptors and occasional inflammatory cell infiltrates in these areas.[108]

Antibody to AChR is lacking in about half of patients with ocular myasthenia only and in about 10% of patients with typical generalized myasthenia. In the latter group, about half the patients have circulating antibody to MuSK, a tyrosine kinase in the motor end plate membrane. Antibodies to one of two intracellular proteins (titin and the ryanodine receptor) or the internal end plate protein rapsyn have been detected in some patients with myasthenia.[108,109]

Two approaches to drug therapy are available for myasthenia. Agents such as neostigmine and pyridostigmine inhibit degradation of acetylcholine at the neuromuscular junction and thereby enhance its action on remaining receptors. Immunosuppressive drugs, such as prednisone and azathioprine, are also used to reduce damage to receptors through either general anti-inflammatory properties or decreased antibody levels.[108,109]

Surgical treatment is also used. The incidence of malignant thymoma is increased among patients with myasthenia. Some of these patients improve after surgical resection of the thymus. This observation stimulated trials of thymectomy in patients not known to have tumors, and these patients may experience disease remission as well.[108,109]

Given the relation between circulating antibody, pathology, and symptoms in myasthenia, TPE has seemed a reasonable approach to therapy.[112] A controlled trial has never been published, but numerous open trials have suggested that the therapy can bring about rapid symptomatic improvement in concert with lower levels of circulating anti-AChR antibody. TPE has also been effective in patients who test negative for AChR antibody, perhaps suggesting that not all pathogenic antibodies are detected by this assay.[108,109]

As a result of this universally favorable experience, TPE is widely accepted as a therapy for myasthenia. It is not, however, recommended for all patients. Rather, it is reserved for those with severe disease and those who either do not respond to other therapies or cannot tolerate them. Patients whose respiration, deglutition, or locomotion is inadequate are good candidates for the rapid improvement brought by TPE, even at initial treatment.[113] TPE can also be useful to optimize muscle function before surgery, especially thymectomy.[114] Occasional patients do best with regular TPE at 2- to 4-week intervals in addition to maintenance drug therapy.[115] Semiselective adsorption of IgG with protein A-Sepharose has been tried in myasthenia, also with favorable results.[116–120]

Myasthenia may also respond to IVIG.[121] Although no randomized trials have been done to prove efficacy, a controlled study compared IVIG with TPE in 87 patients. Either three or five infusions of IVIG at 0.4 g/kg were found equivalent to three TPE treatments. A shorter median time to response for TPE-treated patients (9 days vs 15 days) did not achieve statistical significance ($P = 0.14$).[122] A multicenter retrospective chart review found significantly better ventilatory status at 2 weeks and functional status at 1 month in patients treated with TPE.[123]

Lambert-Eaton Myasthenic Syndrome

Lambert-Eaton myasthenic syndrome (LEMS) is characterized clinically by fatigue and weakness. It differs from MG in that oculomotor and bulbar symptoms are rarely prominent, but signs of dysautonomia, such as dry mucous membranes and orthostatic hypotension, are common. LEMS most often occurs as a paraneoplastic syndrome. About 60% of cases are associated with small cell lung cancer, and associations with other tumors are also known. In many cases, the neuromuscular symptoms antedate any other sign of tumor.[124–126]

LEMS also is a disease of the neuromuscular junction, but the defect is in the nerve cell ending instead of the muscle cell. LEMS is caused by circulating antibody directed against the voltage-gated calcium channels (VGCCs) in the nerve terminus that mediate electrical events in neuromuscular impulse transmission. The physiologic result is a reduction in the amount of acetylcholine released by depolarization events, with consequent weakness in affected skeletal muscles as well as dysfunction at some autonomic nerve endings.[127,128] The LEMS antibodies appear to be restricted to the P/Q subset of VGCCs.[127]

Curiously, cholinesterase inhibitors are less effective in LEMS than in MG. Agents that prolong nerve action potentials by blocking voltage-gated potassium channels may improve muscle strength in LEMS patients, presumably by enhancing acetylcholine release; 3,4-diaminopyridine is currently considered the most useful of these.[129,130] Immunosuppressive drugs such as cortisone and azathioprine may be helpful in LEMS, and paraneoplastic cases may respond to specific antitumor therapy.[130–132] TPE has been helpful in LEMS. Responses are often slower and more modest than those seen in MG, suggesting that more time is required to heal a damaged nerve ending.[129,132] IVIG has also been reported to be effective in trials in both the short and long term.[130]

Other Paraneoplastic Neurologic Syndromes

A number of distinct neurologic syndromes are associated with malignant tumors and are characterized by circulating antibody to structures in the nervous system. Paraneoplastic encephalomyelitis is characterized by seizures, mental changes, and cerebellar and autonomic dysfunction. It is often associated with anti-Hu (also called ANNA-1), an antibody to a 38- to 40-kDa antigen found in the nuclei of neurons and of small cell lung cancer cells. Paraneoplastic cerebellar degeneration produces ataxia, dysarthria, and downbeating nystagmus. It may arise in association with ovarian, breast, and small cell lung cancers as well as with Hodgkin's disease. About 40% of patients have circulating anti-Yo, an antibody to 34- and 62-kDa antigens in Purkinje cells. Paraneoplastic opsoclonus-myoclonus syndrome is characterized by both vertical and horizontal dysrhythmic conjugated eye movements. It may occur in children with neuroblastoma and in adults with lung, breast, or other tumors. Cases seen with breast or gynecologic cancers may have circulating anti-Ri (also called ANNA-2), an antibody to 55- and 80-kDa antigens in neuronal nuclei. Cancer-associated retinopathy causes photosensitivity and gradual visual loss. It is associated with anti-CAR, an antibody to antigens shared by retinal neurons and small cell lung cancer cells.[133–135]

Treatment of these syndromes is difficult. They seldom respond well to antitumor measures, even when these are otherwise effective, or to pharmacologic immunosuppression.

TPE has been used in a number of these cases, usually with disappointing results.[133,134]

Stiff-Person Syndrome

Stiff-person syndrome (SPS), originally known as stiff-man syndrome, is characterized by progressive rigidity or spasms of trunk and proximal limb muscles or both.[136,137] About 60% of patients have high titers of circulating antibody to glutamic acid decarboxylase (GAD), which is the rate-limiting enzyme in the synthesis of γ-aminobutyric acid (GABA), the neurotransmitter for the majority of inhibitory central nervous system (CNS) synapses.[137–139] When present, anti-GAD is believed to have a pathogenic role even though neuronal GAD, as a cytoplasmic enzyme, should be inaccessible to antibody. CNS histology is normal in SPS, suggesting that anti-GAD causes functional rather than structural changes. Pathogenesis is more uncertain in patients who lack antibody to GAD.[137–139]

About 5% of cases are associated with cancer, usually breast cancer. Instead of anti-GAD, most such patients have antibody to amphiphysine, a 128-kDa presynaptic vesicle protein.[138,140,141] A few have antibody to a postsynaptic protein called gephyrin that is associated with receptors for GABA and for glycine, another inhibitory neurotransmitter.[142]

Symptoms often respond to diazepam or other agents that increase CNS GABA levels. Immunomodulatory therapies such as prednisone, TPE, and IVIG have also seemed beneficial in individual cases, but no controlled trials have been performed.[143] In paraneoplastic cases, improvement may follow removal of the malignancy.

Other Non-neoplastic Disorders with Anti-CNS Antibodies

Rasmussen encephalitis is a rare, acquired disorder that may begin in childhood, adolescence, or adulthood, often after a viral infection. Seizures are a prominent clinical feature but, unlike patients with idiopathic epilepsy, patients with Rasmussen encephalitis develop progressive, usually unilateral neurologic deficits including hemiparesis and mental retardation. Histopathologic studies show inflammation and atrophy of brain tissue, usually confined to one hemisphere. Children progress faster and have more atrophy and more severe hemiparesis than do adolescents and adults.[144,145]

Studies have revealed circulating IgG antibody to the Glu R3 receptor for the CNS neurotransmitter glutamate,[146] as well as cytotoxic T cells reactive against neurons.[147] It is hypothesized that the autoantibodies arise in response to a crossreactive microbial antigen.[148] Treatment with either TPE,[149] IVIG,[150] and/or other immunosuppressive therapies[151] has been reported to bring temporary clinical improvement.

Sydenham chorea is an acquired movement disorder of children that follows group A streptococcal infection.[152] Many children with typical chorea also exhibit obsessive-compulsive symptoms,[153] and some children who have obsessive-compulsive disorder, tics, and other neurologic symptoms without chorea have evidence of streptococcal infection (pediatric autoimmune neuropsychiatric disorders associated with streptococcal infection [PANDAS]).[154]

Some evidence suggests that an antibody response to streptococcal antigens that crossreacts with antigens in the basal ganglia could mediate symptoms in some patients,[155–157] although this is not universally accepted.[158] Small controlled trials have indicated that TPE and IVIG may both be beneficial in Sydenham chorea[159] and in PANDAS.[160] More recent studies have linked a number of other movement and behavior disorders to antibodies against antigens in the basal ganglia that arise after a streptococcal infection.[161] Trials of TPE or other immunosuppressive therapies have not yet been reported in these conditions.

Multiple Sclerosis

Multiple sclerosis (MS) is a demyelinating disease of the CNS that results in localized neurologic dysfunction. Two clinical patterns can be distinguished. About 70% of patients have acute attacks that resolve partially or fully over time (relapsing-remitting). The other 30% have gradual but continual progression of disease (chronic progressive). Attack frequency in relapsing-remitting MS tends to decrease with disease duration, and some patients may change to a chronic progressive pattern.[162]

Discrete plaques of demyelination in white matter are the pathologic hallmarks of MS. These areas, which are easily visualized on magnetic resonance imaging (MRI), are initially inflammatory but progress to fibrosis.[162] The mechanism of their appearance remains a mystery, but most experts in the field suspect involvement of the immune system. An animal model of MS (experimental allergic encephalomyelitis [EAE]) can be induced by immunization with myelin basic protein (MBP) or other myelin proteins. EAE appears to be mediated by T cells and can be passively transferred with T cells from immunized animals.[163,164] Most evidence points to a disordered cellular immune response in MS as well.[165] Recent studies have demonstrated antibodies to MBP or myelin oligodendrocyte glycoprotein (MOG) or both in CNS lesions[166] and in serum of some MS patients.[167] Although they are predictive of progression to MS in patients with a clinically isolated demyelinating event,[168] such antibodies do not produce MS in experimental animals, and thus the role of circulating antibody in pathogenesis, if any, remains unclear.[165]

Treatment of MS is problematic. Observational studies are complicated by the natural tendencies for acute attacks to subside and for attack frequency to decline, as well as other spontaneous fluctuations in disease activity. Clinical measurement tools such as the Expanded Disability Status Scale have been devised to quantify improvement or progressive disability, or both. These bring some objectivity to clinical studies but are arithmetically arbitrary and subject to interrater variability.[162,169]

Immunosuppressive and immunomodulatory drugs have been the mainstay of pharmacologic treatment in MS. Resolution of acute attacks is thought to be promoted by short courses of either corticosteroids or adrenocorticotropic hormone. These agents may promote faster return of normal nerve conduction by lessening edema and inflammation around new plaques.[162] It is doubtful whether the relentless progression of disability is halted by these measures, although vigorous use of intravenous steroids for optic neuritis may delay the onset of frank MS that it often portends.[170,171] Cyclosporin, total lymphoid irradiation, and cytotoxic immunosuppressants such as azathioprine and cyclophosphamide provide only modest benefits that may not warrant their attendant risks.[171] Low-dose methotrexate[171]

has also been tried. Mitoxantrone, interferon-β, and glatiramer acetate (a mixture of synthetic polypeptides that may modulate immune responses to myelin basic protein) are immunomodulatory agents that have been shown to reduce the frequency of acute attacks and the appearance of new lesions on MRI.[172,173]

IVIG has also been tried in MS. Prophylactic administration was reported to reduce the frequency of attacks in open trials. In three controlled trials, a decrease in the frequency of attacks was noted.[174–176] MRI was not monitored in one study[174]; in another, fewer gadolinium-enhancing lesions were found in IVIG-treated patients[175]; in the third, the number of lesions seen without enhancement was the same after 2 years in both treatment and control groups.[176] Recent guidelines state that IVIG is of little benefit in MS.[173]

The rationale for use of TPE in MS is unclear because so little evidence implicates any circulating factor in the etiology of acute attacks or chronic progression. TPE has been used, however, and uncontrolled studies have reported encouraging results.[177–179] In controlled studies, it has been more difficult to discern benefit, even with vigorous TPE regimens.[180,181] The first randomized double-blind sham-controlled study in chronic progressive MS was reported to show significant benefit for patients receiving TPE in addition to cyclophosphamide and prednisone.[182] The study was subsequently questioned because of anomalies in statistical analysis and because extraordinary recoveries in several of the TPE patients have not been reproduced in subsequent trials, suggesting that some patients with the relapsing-remitting form were inadvertently misclassified and entered into the trial.[183–185] Two later sham-controlled trials did not show convincing benefit.[186,187] Although TPE may yet be found useful in some subset of MS patients, such as previously nondisabled individuals with prolonged severe demyelination unresponsive to other therapies,[188,189] most neurologists view it as controversial at best. The Therapeutics and Technology Assessment subcommittee of the American Academy of Neurology and the MS Council for Clinical Practice Guidelines have classified TPE as "of little or no value" in progressive MS and of uncertain value in acute severe demyelination in previously nondisabled individuals.[173]

THERAPEUTIC PLASMA EXCHANGE IN HEMATOLOGIC AND ONCOLOGIC DISORDERS

Blood is the organ that can be most directly manipulated by therapeutic apheresis, and TPE has been tried in a variety of hematologic and oncologic conditions. These are listed in Table 55–4 along with the indication categories assigned by ASFA and AABB.[40,41]

Monoclonal Proteins

In addition to peripheral neuropathy, four other syndromes associated with monoclonal immunoglobulins are regarded as clinical indications for TPE. All five are listed in Table 55–5. The three syndromes that almost always occur in the setting of a malignant B-cell disorder are discussed here, and cryoglobulinemia is discussed in a later section.

The hyperviscosity syndrome was the first condition to be treated successfully with manual plasmapheresis, the precursor to TPE.[2,3] The full-blown syndrome includes neurologic symptoms, a bleeding diathesis, a distinctive retinopathy characterized by alternating dilated and constricted segments in retinal veins (link-sausage veins), and hypervolemia related to an expanded plasma volume. Symptoms seldom occur if the relative serum viscosity is less than 4 and become more likely when it exceeds 6. The syndrome is most often seen in patients with IgM paraproteins in the context of Waldenström macroglobulinemia but may occur in multiple myeloma as well.[190–192]

At higher paraprotein levels, the relationship between viscosity and paraprotein concentration is nonlinear such that a relatively large change in viscosity may follow a relatively small change in paraprotein concentration. As a consequence, the two-unit manual plasmapheresis technique available in the 1950s could lower an elevated viscosity enough to relieve symptoms. When combined with the fact that most affected patients have IgM paraproteins that are roughly 80% intravascular, this nonlinear relation also predicts that a 1 plasma volume automated exchange will provide a wide margin of safety and can be done less often in the hyperviscosity syndrome than is necessary in many other conditions.[190,193] Viscosity measurements should guide therapy, of course, but treatment every 1 to 2 weeks is often adequate.

Interference by paraprotein molecules in platelet and clotting factor interactions may occur even in the absence of hyperviscosity. Coagulopathies are found in 60% of patients

Table 55–4 ASFA/AABB Indication Categories for Therapeutic Plasma Exchange in Hematologic-Oncologic Disorders

Disorder	Indication Category*
Myeloma/paraproteins/hyperviscosity	II
Myeloma/acute renal failure	II
Hemolytic disease of the newborn	III
ABO-incompatible marrow transplant	II
Platelet alloimmunization and refractoriness	III
Thrombotic thrombocytopenic purpura	I
Hemolytic-uremic syndrome	III
Post-transfusion purpura	I
Idiopathic thrombocytopenic purpura (IA)	II
Autoimmune hemolytic anemia	III
Aplastic anemia/pure red blood cell aplasia	III
Coagulation factor inhibitors	II

Table 55–5 Paraprotein-Related Indications for Therapeutic Plasma Exchange

Indication	Implicated Ig classes
Hyperviscosity	IgM > IgG/IgA
Coagulopathy	IgM > IgA > IgG
Myeloma kidney	Light chains
Neuropathy	IgM > IgG/IgA
Cryoglobulinemia	
Type I	IgM/IgG/IgA
Type II	IgM >> IgG/IgA

Ig, immunoglobulin.

with macroglobulinemia, 40% of patients with IgA myeloma, and 15% of patients with IgG myeloma.[194] Should they prove clinically significant, TPE therapy can help to restore adequate hemostasis.

Renal failure occurs in 3% to 15% of myeloma patients and carries a poor prognosis. In many such cases, renal biopsy demonstrates accumulation of free light chains in renal tubules. With normal renal function, urinary excretion of light chains far exceeds the amounts that could be removed by TPE, but in renal failure, the reverse may be true.[195–198] Two controlled studies have shown higher rates of recovery of renal function in patients who received TPE therapy. In one study, three of seven dialysis-dependent patients who received TPE recovered renal function whereas none of five control patients did.[199] In the other, 13 of 15 patients in the treatment group recovered renal function compared with only 2 of 14 control subjects.[200] Thus TPE is recommended for such patients.[201]

Alloantibodies to Blood Cells

Alloantibodies to red blood cells and platelets may contribute to a disease process in a number of situations. Antibody removal has been used as a treatment in several of these pathologic states.

Hemolytic disease of the newborn was one of the first conditions to be approached with automated apheresis instruments.[8–10,202] Efforts were made to lower anti-D titers by TPE in sensitized D-negative mothers carrying a D-positive fetus in the hope of ameliorating fetal red blood cell destruction. The incidence of this condition has decreased dramatically as prophylaxis with Rh immune globulin has become more widespread, and intrauterine transfusion with D-negative red blood cells has proved to be a more effective treatment for an affected fetus.[203] TPE is seldom used in this circumstance now, but it may still be helpful in pregnancies with early evidence of fetal involvement because intrauterine transfusion is not feasible before about 18 weeks of gestation.[204,205] Early institution of TPE was associated with successful delivery after multiple prior abortions in compelling case reports involving anti-M[206] and anti-P.[207]

TPE has also been used to remove isoagglutinins in the context of transplantation. Allogeneic stem cell transplantation across a major ABO barrier (e.g., group A donor into group O recipient) is feasible if a hemolytic transfusion reaction to red blood cells in the transplant can be avoided. For bone marrow transplants, this was first accomplished by exhaustive pretransplantation TPE of the recipient to reduce the relevant isoagglutinin titer.[208] Immunoadsorption columns containing A or B substance have subsequently been used.[209] Ultimately, however, it has proved preferable simply to remove most of the red blood cells from the bone marrow graft before transplantation.[210] Peripheral blood stem cell grafts contain smaller quantities of red blood cells and can usually be infused safely without any manipulation. Red blood cell engraftment is sometimes delayed after ABO-incompatible transplantation, however, and TPE has been tried, both before transplantation to avoid delayed engraftment and after transplantation to correct it, with uncertain results in both cases.[211–213] Resolution of delayed engraftment after donor leukocyte infusions has also been reported.[214]

Solid-organ transplantation across a major ABO barrier can result in hyperacute rejection and is usually avoided for this reason. In desperate circumstances, however, considerations of organ availability have sometimes dictated use of an ABO-incompatible liver after pretransplantation TPE of the recipient, often with a satisfactory outcome.[215–217] More recently, the prolonged shortage of donor kidneys has been addressed by elective transplantation of kidneys from informed living donors across major ABO barriers.[218–220] Both A_2 and non-A_2 organs have been successfully engrafted. Pretransplant immunosuppressive regimens include TPE to lower isoagglutinin titers.[221]

Organ transplantation across a minor ABO barrier (e.g., group O donor into group A recipient) does not increase the risk of rejection; however, it is sometimes followed, within 1 to 3 weeks after transplantation, by a hemolytic anemia related to isoagglutinin secretion by B lymphocytes carried in the transplanted organ. Hemolysis mediated by these "passenger lymphocytes" is most often seen in heart-lung or liver transplantation, where the volume of lymphoid tissue transplanted is relatively high.[222] It may, however, be seen after renal transplantation and may involve anti-D.[223] Severe hemolysis in this setting may be partially ameliorated by TPE in combination with compatible red blood cell transfusion.[224]

Alloimmunization to platelets can cause clinical refractoriness to platelet transfusions.[225] Removal of antibody has been attempted, both with TPE[226] and with a protein A-silica column.[227,228] IVIG has also been tried.[229–231] However, the results have been inconclusive and transfusion of compatible platelets is still the best option.

Thrombotic Thrombocytopenic Purpura and Hemolytic-Uremic Syndrome

Thrombotic Thrombocytopenic Purpura

Thrombotic thrombocytopenic purpura (TTP) is characterized by microangiopathic hemolytic anemia and thrombocytopenia, often severe. Fever, CNS changes, and renal abnormalities may be seen in advanced cases, although frank renal failure is uncommon.[232] A rare relapsing form usually begins in childhood, but most cases are sporadic and occur in adults.[233] Women are predominantly affected, accounting for 70% of cases.[234] TTP is usually idiopathic, but the syndrome may be seen in association with other illnesses, such as SLE[235] and HIV infection.[236] Idiopathic TTP was formerly associated with a mortality rate of 95%, but empirical studies in the 1970s and 1980s demonstrated much better survival in patients who received TPE with plasma replacement. Some patients, including children with the relapsing form of the disease, respond to simple plasma infusion.[233]

A convincing account of the pathogenesis of TTP has been offered. It involves a plasma enzyme (a metalloproteinase designated ADAMTS 13) that cleaves the ultralarge von Willebrand factor (ULvWF) multimers secreted by endothelial cells, yielding the smaller polymers found in normal plasma. Children with relapsing TTP have an inherited deficiency of this enzyme,[237] whereas an acquired deficiency, related to the presence of an autoantibody that inhibits the enzyme, has been found in idiopathic adult cases[238,239] and some SLE[240] and HIV-associated[241] cases. In either instance, persistence of ULvWF in the circulation or on the surface of endothelial cells or both apparently promotes inappropriate adherence of platelets to endothelial cells and to each other, leading to consumptive thrombocytopenia and microvascular obstructions. The latter cause mechanical trauma to red

blood cells and varying degrees of end-organ ischemia.[233] Periodic plasma infusion may abort or prevent attacks in congenitally deficient patients.[237] Idiopathic cases respond better to TPE (78% response rate vs 63% for plasma infusion in a Canadian study),[242] presumably because exchange removes inhibitory antibody as well as supplying the deficient enzyme. Exchanges are usually carried out daily until the platelet count and lactate dehydrogenase (as a marker of hemolysis) have normalized.

Various immunosuppressive measures, such as glucocorticoid therapy,[243] vincristine,[244] rituximab,[245] and splenectomy,[246] have been advocated as adjunctive treatments. Discovery of an autoimmune etiology provides support for their use in idiopathic but not in congenital cases. A syndrome similar to TTP has been identified in some patients taking the antiplatelet drug ticlopidine. Autoantibody-induced deficiency of the metalloproteinase has been demonstrated in patients with this syndrome,[247] and TPE has been reported to improve survival (76% survival vs 50% for patients without exchange in a retrospective study).[248]

Hemolytic-Uremic Syndrome

The hemolytic-uremic syndrome (HUS) is characterized by microangiopathic hemolysis, renal insufficiency, and mild to moderate thrombocytopenia.[249] In children, it may occur in a self-limited form that follows infection with a verotoxin-producing *Escherichia coli* (diarrhea + or D+); however, some pediatric cases lack this association (D–).[250,251] Familial and nonfamilial forms affect adults.[238] Nonfamilial cases may be idiopathic or may be associated with prior chemotherapy or stem cell transplantation.[252]

Because of overlapping manifestations that sometimes preclude distinction on clinical grounds alone, it has long been supposed that the pathogenesis of HUS was similar to that of TTP. Largely on this basis, TPE and protein A column therapy have been recommended for D-childhood HUS and for adult HUS. Although this is a prevalent standard of care, responses have generally been less favorable than in TTP, particularly in thrombotic microangiopathy associated with chemotherapy and transplantation.[233,253–255]

Levels of the vWF-cleaving metalloproteinase have now been studied in adult patients with both familial and nonfamilial forms of HUS. Neither severe deficiency nor inhibitory activity has been found.[238] Another study in patients with clinically uncategorized thrombotic microangiopathy compared 50 patients with severe ADAMTS 13 deficiency to 57 patients who were not severely deficient. The severely deficient patients had a lower median platelet count (13,000/μL vs 44,000/μL; $P < 0.001$), a lower median creatinine (1.3 mg/dL vs 2.7 mg/dL; $P < 0.001$), and a higher rate of relapse (16 of 46 vs 4 of 47 evaluable patients; $P < 0.01$).[256] Thus the prior supposition of a shared pathogenic mechanism for TTP and HUS would seem to be in error. Deficiency of complement factor H has been identified in some patients with familial HUS.[257–259] This might provide some rationale for plasma therapy; however, for most cases, the role of TPE is unclear at this time. Similar comments apply to the HELLP syndrome of hemolysis, elevated liver enzymes, and low platelets in pregnant women,[260] which shares clinical features with TTP, HUS, and preeclampsia.

ADAMTS 13 Assays

Several techniques have been devised to measure ADAMTS 13 activity in patient plasma and to detect inhibition of exogenous enzyme by patient plasma. End points after incubation of vWF with a putative enzyme or inhibitor source include electrophoretic assessment of vWF multimer size, extent of collagen binding by residual vWF, residual ristocetin cofactor activity, and immunoradiometric quantitation of cleavage sites.[261] Currently none of these assays is widely available to clinicians with a rapid turnaround time. This inaccessibility alone limits the value of such assays in clinical decision making. Furthermore, in multilaboratory comparative studies, the intra- and interlaboratory precision and accuracy of results obtained on replicate samples have been far from ideal (with coefficients of variation as high as 83%, even in the most respected laboratories), although most laboratories seem capable of recognizing severely deficient samples, variously defined as containing less than 5% or less than 10% of the ADAMTS 13 activity level in pooled normal plasma.[262,263] Interlaboratory variability in detection and quantitation of ADAMTS 13 inhibitors has been even more disappointing.[262]

Several retrospective surveys have questioned the value of ADAMTS 13 inhibitor assays in recognizing TTP, in differentiating TTP from HUS, and/or in predicting responsiveness to TPE.[264,265] Given the limitations of current assays and the disagreement about what degree of deficiency is "clinically significant," it is perhaps not surprising that their predictive value is suboptimal. Other confounding factors may also contribute to apparent discrepancies. These might include (1) alternative pathogenic mechanisms in some patients (for example, an antibody that blocks access of ADAMTS 13 to endothelial cell membranes could theoretically produce a TPE-responsive TTP syndrome with normal plasma enzyme levels[233]); (2) inability to eliminate very high titer inhibitors even with aggressive TPE, as is seen with some factor VIII inhibitors; and (3) spontaneous resolution of illness or response to concurrent therapies such as corticosteroids in patients with disease processes unrelated to ADAMTS 13 who nevertheless undergo TPE. Despite these reservations, it seems certain that the elucidation of ADAMTS 13 deficiency was a major advance in understanding the pathogeneses of TTP. It is likely that accurate assays for ADAMTS 13 activity and inhibitors that are widely available and have short turnaround times would be useful in evaluation of patients with thrombocytopenia and microangiopathic hemolysis.[240,265,266] However, prospective controlled studies and/or additional clinical experience will be necessary to assess fully the value of such assays.

Post-transfusion Purpura

Post-transfusion purpura (PTP) is a rare syndrome in which the platelet count decreases abruptly to dangerously low levels about 1 week after an allogeneic transfusion. Patients who develop the syndrome lack the common allele for one of the platelet-specific glycoprotein antigens, most often the human platelet-specific antigen 1a (HPA-1a) on glycoprotein IIIa. Most affected patients have had multiple pregnancies or prior transfusions and have been immunized thereby to the platelet-specific antigen coded by the prevalent allele. The transfusion that precipitates the illness appears to stimulate an anamnestic response with an increasing IgG antibody titer, most often anti–HPA-1a. PTP is self-limited and usually resolves without treatment in several weeks; however, bleeding complications, including fatal CNS hemorrhage, may occur.[267–269]

Although PTP is linked to a platelet-specific alloantibody response, the mechanism of extensive destruction of antigen-negative autologous platelets remains obscure. The following four possibilities have been proposed: (1) platelet antigen-antiplatelet antibody immune complexes bind to autologous platelets and mediate their destruction; (2) autologous platelets adsorb soluble alloantigen derived from the transfusion; (3) a simultaneous platelet autoantibody response occurs; and (4) a broad alloimmune response produces antibodies that crossreact with autologous platelets.[270]

Treatment of PTP is advisable because many patients have bleeding complications. High-dose corticosteroids are usually given empirically, and pulse methylprednisolone at 1 g/day has been reported effective. Platelet transfusions, even those from antigen-negative donors, do not increase the platelet count and may cause severe reactions. Daily TPE usually promotes an increase in platelet count within a few days and is considered an effective treatment for this reason, even though controlled trials have not been done.[271] Exchanges usually include FFP replacement to avoid a superimposed humoral coagulopathy. IVIG leads to similarly prompt increases in platelet count and has become the favored treatment modality for this group of patients.[272]

Idiopathic Thrombocytopenic Purpura

Idiopathic thrombocytopenic purpura (ITP) is an autoimmune illness affecting platelets. Most patients have an IgG autoantibody directed against a platelet membrane glycoprotein antigen. ITP sometimes accompanies warm autoimmune hemolytic anemia (Evans syndrome). A pediatric form of ITP is acute and self-limited; recovery is the rule with or without treatment. Adult cases, most of which occur in women, seldom remit without therapy, and most progress to the chronic form of the disease. An ITP-like syndrome also occurs in association with SLE and HIV.[273]

The goal of treatment in ITP is prevention of bleeding. Because most platelets circulating in ITP patients are relatively young and more hemostatically active, avoidance of hemorrhage can be accomplished without normalization of the platelet count. Corticosteroids, splenectomy, and IVIG are the mainstays of therapy.[273] Some favorable anecdotal reports of TPE in ITP appeared in the 1970s.[274,275] One small controlled trial suggested a lower rate of splenectomy in patients receiving exchange,[276] whereas a retrospective survey found little difference.[277] In the absence of confirmatory trials, however, enthusiasm for this approach has waned, and TPE is seldom used in ITP.

Favorable responses to protein A–silica column treatment have been reported, first in ITP associated with HIV infection[278] and later in patients with chronic ITP without HIV.[279] The mechanism of action of protein A in this disease is uncertain. A subtractive mechanism involving antiplatelet antibody is unlikely because responses have been reported with treatment of as little as 250 mL of plasma per week. Bearing this uncertainty in mind, the protein A–silica column remains an option for chronic ITP refractory to more standard therapies.

Autoimmune Hemolytic Anemia

Autoimmune hemolytic anemia (AHA) is caused by autoantibodies to red blood cells. Such antibodies are either cold or warm agglutinins. Cold agglutinins are usually IgM antibodies directed against the I/i antigens; they bind preferentially at low temperatures and produce the syndrome of complement-mediated intravascular hemolysis known as cold agglutinin disease (CAD). Warm agglutinins are usually IgG and are often directed against an antigen that is not expressed on Rh_{null} cells. They bind better at body temperature and produce a predominantly extravascular hemolytic syndrome (warm autoimmune hemolytic anemia [WAHA]). AHA can be idiopathic but may also be associated with an infection, a lymphoproliferative disorder, or another autoimmune disease.[280,281]

Most cases require treatment. Standard therapy is aimed at inhibiting antibody production or reducing destruction of sensitized cells, or both. Corticosteroids, IVIG, and splenectomy are often effective in WAHA, and other immunosuppressive drugs may be tried if these measures fail.[280] All approaches are less successful in CAD.[281]

TPE to deplete circulating antibody has been tried in both WAHA and CAD when conventional treatments have failed.[282–288] IgM antibodies in CAD are predominantly intravascular and only loosely bound to cells; thus their removal by TPE should be relatively efficient. Such therapy, when added to conventional drug treatment, has been reported to transiently reduce antibody titers and transfusion requirements in CAD. In WAHA much of the circulating antibody is bound to red blood cells; TPE has also been tried in this disorder, but it is less likely to be helpful.

Aplastic Anemia and Pure Red Blood Cell Aplasia

Aplastic anemia and pure red blood cell aplasia are bone marrow disorders. The former leads to pancytopenia, whereas in the latter, only reticulocytopenic anemia results. At least some cases of both conditions are likely to be immunologically mediated. Allogeneic bone marrow transplantation is the preferred treatment for aplastic anemia if a suitable donor is available, but immunosuppressive therapies, such as corticosteroids, cytotoxic drugs, cyclosporin, and antithymocyte globulin, are effective in some cases.[289–291]

In a minority of patients, it is possible to demonstrate a serum factor, probably antibody, that is inhibitory to the growth of relevant marrow-derived precursor cells in culture.[292] These observations provided an explicit rationale for TPE, and this therapy has been reported in a handful of cases in both disorders. Results in aplastic anemia have been mixed, with responses more likely in patients demonstrating serum inhibitory activity.[292–294] In pure red blood cell aplasia, all reported instances of TPE treatment have led to improvement, which is sometimes quite dramatic in patients with serum inhibitory activity.[295–298] Thus although TPE is not a primary therapy for either disorder, it is an option for patients who have not responded to more conventional treatment, especially those who have serum inhibitory factors.

Coagulation Factor Inhibitors

Coagulation factor inhibitors are IgG antibodies directed against components of the humoral clotting cascade. They inactivate the targeted factor and interfere with clotting. They may be autoantibodies that arise in individuals with no prior bleeding disorder. Alternatively, they may be alloantibodies arising in genetically deficient patients as a result of exposure to a "foreign protein" in the course of factor-replacement

therapy.[299,300] Factor VIII is the clotting protein most often affected by antibodies of either type.

The goals of treatment for patients with inhibitors are, first, control of individual bleeding episodes and, eventually, suppression of inhibitor synthesis.[301,302] Depending on the inhibitor titer, the first goal can usually be achieved by infusion of high doses of human factor VIII, porcine factor VIII (which is usually only partially crossreactive with anti–human factor VIII antibodies),[303] or, for patients with the highest titers, factor VIII–bypassing products, including recombinant factor VIIa.[304] TPE with plasma replacement may be used during a bleeding episode to reduce inhibitor titers enough to allow infused human or porcine factor VIII to circulate and bring about hemostasis.[305–307] Immunoadsorption with protein A–Sepharose may also be effective for this purpose.[308] Suppression of inhibitor synthesis is approached with immunosuppressive measures, including high-dose corticosteroids, cytotoxic agents,[309] cyclosporin,[310] IVIG,[311] and rituximab.[312,313] Tolerance-inducing protocols have been devised for congenitally deficient patients with alloimmune inhibitors.[314,315] These involve regular infusion of exogenous factor VIII. In the so-called Malmö protocol, extensive TPE or IgG depletion with protein A–Sepharose column procedures is used to reduce the inhibitor titer at the onset of treatment so that infused factor can circulate.[316] Patients with inhibitors usually need frequent, large (two or three plasma volumes) exchanges with FFP replacement. Central venous access is frequently required; catheter placement in the context of a refractory bleeding disorder is challenging to all concerned and often mandates use of a factor VIII–bypassing product for wound hemostasis.[317]

TPE has also been reported for treatment of patients with antiphospholipid antibodies.[318] These may interfere with in vitro assays of coagulation, such as the partial thromboplastin time. However, unlike the inhibitory antibodies described earlier, they usually promote inappropriate coagulation in vivo and cause thrombotic events.

THERAPEUTIC PLASMA EXCHANGE IN OTHER IMMUNOLOGIC DISORDERS

TPE has been tried in a number of rheumatic diseases and other diseases that are considered to have an immune or autoimmune etiology. These are listed in Table 55–6 along with the indication categories assigned by ASFA and AABB.[40,41]

Cryoglobulinemia

Cryoglobulins are defined as serum proteins that precipitate reversibly at 4° C, although some precipitate at higher temperatures. The precipitates always contain immunoglobulins, and immunoelectrophoretic or immunofixation analysis allows distinction of three types.[319]

Type I cryoglobulins consist of a single species of monoclonal immunoglobulin. These are usually found in myeloma, Waldenström macroglobulinemia, or other lymphoproliferative disorders (see Table 55–5). Cryoglobulin levels are often quite high (>500 mg/dL) and may cause Raynaud phenomenon or acral necrosis related to microvascular obstruction, as well as other symptoms. Type II cryoglobulins have both a monoclonal and a polyclonal component. The former is usually an IgM*k* with anti-IgG activity that binds polyclonal IgG in an immune complex. These typically produce a lower-extremity cutaneous vasculitis and may cause other, more serious visceral manifestations of immune complex disease. Many cases occur in association with chronic hepatitis C infection.[320] Type III cryoglobulins are mixed polyclonal, often with IgM anti-IgG that binds IgG in immune complexes. These may arise in acute infections, such as hepatitis B, and in severe rheumatoid arthritis or other chronic inflammatory states. Clinical manifestations resemble those of serum sickness.[319,321]

If an associated condition is present, cryoglobulin levels and related symptoms may decrease with treatment of the primary disorder (for example, chemotherapy for myeloma or interferon for hepatitis C virus infection). For idiopathic and secondary cases of mixed cryoglobulinemia, prednisone therapy may be effective in relieving symptoms, and alkylating agents may be useful for patients with severe symptoms resistant to prednisone.[321]

TPE reduces cryoglobulin levels and controls symptoms.[322] It can do so even in the absence of other treatments,[35] but expense and inconvenience usually preclude such use. Plasma exchange therapy should be started promptly for patients with severe acral ischemia or visceral manifestations of vasculitis.[323] In such patients, it can help gain and maintain control of symptoms until aggressive drug therapy takes hold. Patients with chronic ulcers in the setting of cutaneous vasculitis may also benefit.[324] Care should be taken to warm replacement fluids to body temperature before reinfusion.

Rheumatoid Arthritis

Rheumatoid arthritis (RA) is a disease of unknown etiology that is more prevalent in women. It is the most common chronic inflammatory joint disease and a leading cause of disability. Most patients have rheumatoid factor, an IgM autoantibody to IgG; however, because this finding is absent in many otherwise typical cases and because it occurs in other patients who do not have arthritis, it is not thought to be directly involved in pathogenesis.[325]

Conservative treatment of RA includes nonsteroidal anti-inflammatory agents, low-dose oral corticosteroids, and intra-articular steroids. More severely affected patients

Table 55–6 ASFA/AABB Indication Categories for Therapeutic Plasma Exchange in Rheumatic and Other Immune Disorders

Disorder	Indication Category*
Cryoglobulinemia	II
Rheumatoid arthritis (IA)	II
Systemic lupus erythematosus	IV
Systemic vasculitis	III
Polymyositis and dermatomyositis	IV
Goodpasture syndrome	I
Rapidly progressive glomerulonephritis	II
Renal transplantation	
Rejection	IV
Presensitization	III
Recurrent focal glomerulosclerosis	III
Heart transplant rejection	III

IA, protein A-silica immunoadsorption.

eventually receive slow-acting antirheumatic agents that are probably immunomodulatory, such as antimalarials, gold compounds, and methotrexate.[326] Tumor necrosis factor inhibitors have been approved for use in RA, and other cytokine antagonists may be beneficial as well.[326,327]

TPE was tried in RA in the 1970s and 1980s, but controlled trials did not show benefit.[328,329] Subsequent reports of lymphapheresis were published, with or without TPE in addition. Some controlled trials showed significant but short-lived benefit,[330] whereas others did not.[331] In practice, the prospect of no more than a modest chance of only modest benefit from a costly and inconvenient therapy has discouraged treatment with therapeutic apheresis.

A sham-controlled trial of 12 weekly protein A–silica column treatments produced improvement in 33% of 48 treated patients versus only 9% of 43 control subjects. Benefit persisted for about 8 months on average, and a subsequent course was again beneficial in seven of nine initial responders.[332] Although its mechanism of action is unclear, this device has gained Food and Drug Administration (FDA) approval for use in RA, and postmarketing clinical experience is beginning to accumulate.

Systemic Lupus Erythematosus

SLE has been viewed as the prototypical autoimmune disease. The occurrence of antibodies to DNA, especially those specific for double-stranded DNA (anti-ds-DNA), identifies a group of patients who may have autoantibodies to a variety of other determinants. Their clinical syndromes compose a disparate mixture in which skin disease, joint disease, cytopenias, or nephritis may be the sole or dominant manifestation.[333,334]

Immunosuppressive measures are the cornerstone of therapy for SLE. Most patients receive prednisone in varying doses, and those with severe disease may also be given azathioprine or cyclophosphamide.[335,336] The plethora of autoantibodies that seem relevant to clinical signs made SLE an obvious target for plasma-exchange therapy, and it was one of the first illnesses to be treated with automated TPE in the early 1970s. A number of case reports and uncontrolled series suggested a favorable effect.[11,12,337,338]

Lupus nephritis is a particularly devastating expression of SLE in which glomerular deposition of anti-ds-DNA and immune complexes is believed to play a prominent pathogenic role. It thus seemed an attractive context for randomized trials. A controlled trial with only eight patients suggested benefit.[339] However, a multi-institutional randomized controlled trial comparing oral cyclophosphamide plus TPE with oral cyclophosphamide alone failed to show any advantage for the patients receiving TPE.[26] A later international trial included patients with a variety of severe manifestations. It was structured to take advantage of an enhanced sensitivity to a properly timed pulse dose of intravenous cyclophosphamide that was believed to follow removal of pathogenic antibody by TPE.[340] As mentioned earlier, subsequent work with knockout mice deficient for the FcRn receptor suggested that enhanced susceptibility would not occur.[24] In any case, this trial also failed to show any benefit associated with TPE, either in all patients[341] or in a subgroup with nephritis.[342] One group has also reported a higher incidence of infection in SLE patients treated with TPE.[343] Thus several large controlled studies have failed to reveal any worthwhile effect of TPE in SLE.

Systemic Vasculitis

Systemic vasculitis is an inclusive term applied to a group of disorders that cause inflammation in blood vessel walls with resultant ischemic tissue damage. Vasculitis syndromes are conveniently classified on the basis of the size of vessels typically involved, as shown in Table 55–7. Most are of unknown etiology. The presence of immune complexes in some syndromes and of autoantibodies in others, such as antineutrophil cytoplasmic antibodies (ANCAs) found in Wegener granulomatosis (c-ANCA) and polyarteritis (p-ANCA), has lent credence to the notion that humoral immune factors are somehow involved.[344]

Prednisone is the first-line therapy for most vasculitic syndromes. Cyclophosphamide or methotrexate is often added in more severe cases.[345] Randomized controlled trials in renal vasculitis,[346] as well as in a group of patients with polyarteritis or Churg-Strauss angiitis,[347] have shown little evidence that long-term benefit is conferred by addition of TPE to immunosuppressive drug therapy. Nevertheless, it may be requested for patients who are not responding to maximal drug therapy. A recent observational trial revealed good outcomes in patients with polyarteritis nodosa associated with hepatitis B who received TPE in conjunction with an antiviral drug.[348]

Polymyositis and Dermatomyositis

Polymyositis and dermatomyositis are inflammatory diseases of skeletal muscle. A characteristic dermatitis, typically involving the eyelids, knuckles, neck, and shoulders, is also found in the latter condition. Proximal weakness with biochemical evidence of muscle cell enzyme leakage is the usual presentation. The diagnosis is confirmed by characteristic inflammatory histology and immunopathology in a biopsy specimen from an affected muscle. The natural history is progressive fiber loss, eventually leading to profound, irreversible weakness. An autoimmune etiology is suspected, but an antibody specific for skeletal muscle has not yet been implicated in pathogenesis.[349]

Initial treatment is high-dose prednisone, which can often be tapered to levels that are tolerable in the long term. Resistant disease is treated with azathioprine, methotrexate, cyclosporine, or an alkylating agent, or a combination thereof.[349] Controlled trials have also shown that IVIG infusion reduces muscle enzyme levels and improves strength temporarily.[350]

Several uncontrolled series have been interpreted to show that TPE was beneficial, but these were confounded by concurrent

Table 55–7 Classification of Systemic Vasculitis

Cutaneous leukocytoclastic angiitis

escalations in immunosuppressive drug therapy.[351–353] A randomized, controlled trial was reported in which 12 patients received TPE, 12 received lymphapheresis, and 12 received sham apheresis, with no changes in drug therapy.[354] No difference in the response rate was found among the three groups. Thus despite the successes with IVIG, no role for TPE appears obvious in the treatment of polymyositis.

Goodpasture Syndrome

Goodpasture syndrome (GPS) is an illness characterized clinically by rapidly progressive glomerulonephritis and in some cases by pulmonary hemorrhage. Renal biopsy shows crescent formation in many glomeruli on light microscopy and linear subendothelial immune deposits on immunofluorescence and electron microscopy. Lung biopsy may show similar subendothelial deposits. In 95% of cases, the syndrome is associated with circulating antibody that binds to glomerular basement membrane (anti-GBM). These antibodies are directed against a noncollagenous sequence (NC1) of the α-3 chain of a type of collagen (type IV) that is found in appreciable quantities only in renal and pulmonary basement membranes. Untreated GPS progresses quickly and relentlessly, and most patients die of uremia or of complications of lung hemorrhage.[355,356]

Since the classic report by Lockwood and colleagues in 1975,[357] the recommended treatment for GPS has been aggressive TPE combined with high-dose prednisone and cyclophosphamide.[358,359] TPE reduces anti-GBM levels quickly to minimize progression of tissue damage.[360] Exchanges are usually carried out daily and may be continued for 2 weeks. It is therefore prudent to give some FFP replacement in the latter part of each exchange to replete coagulation factors and avoid exacerbations of lung bleeding related to dilutional coagulopathy.[355,356]

The only controlled trial on record failed to show an advantage for GPS patients who received TPE; however, this study has been largely discounted because the TPE schedule (every 3 days) was not sufficiently aggressive and because, despite randomization, the extent of renal damage at entry was not comparable in the TPE and control groups.[361] Early treatment is preferred because it has been noted that patients with dialysis-dependent renal failure at the onset of treatment are not likely to recover renal function.[362,363] A corollary is that patients whose renal biopsies show an irreversible lesion and who do not have pulmonary hemorrhage are unlikely to benefit from TPE.

Other Rapidly Progressive Glomerulonephritis

In addition to GPS, two other categories of rapidly progressive glomerulonephritis (RPGN) exist, as shown in Table 55–8. In both of these, the light microscopic findings are similar to those in GPS with severe glomerular inflammation and crescent formation. Some cases may even have associated lung hemorrhage. The distinction among RPGN subcategories rests on immunofluorescence microscopy and electron microscopy, which show granular (vs linear in GPS) subendothelial immune deposits, usually taken to be immune complexes, in one group of patients and absence or relative scarcity of immune deposits in the other (pauci-immune RPGN). Patients in each group may have isolated, idiopathic renal disease or may have accompanying features that suggest a diagnosis of systemic vasculitis (for example, mixed cryoglobulinemia or Henoch-Schönlein purpura for granular-immune complex RPGN and microscopic polyangiitis or Wegener granulomatosis for patients with pauci-immune RPGN, many of whom test positive for ANCA).[364]

Table 55–8 **Subtypes of Rapidly Progressive Glomerulonephritis (RPGN)**

Nomenclature	Quality of Subendothelial Immune Deposits
Goodpasture syndrome	Linear
Immune complex RPGN	Granular
Pauci-immune RPGN	Scant or none

Because treatments for the two categories are similar, some trials and series have included patients with both types of RPGN.[365,366] Virtually all patients receive prednisone, and most receive cyclophosphamide, either orally or intravenously. TPE has been used extensively in patients with both types of disease, and early uncontrolled series tended to credit it with a beneficial effect. Two controlled trials, one published in 1988[367] and the other in 1992,[368] showed no advantage overall for patients who received TPE in addition to immunosuppressive drugs. However, a separate analysis of the small subgroup in the second study who had dialysis-dependent renal failure suggested that such patients have a better chance of recovering renal function if they receive TPE.[368] A comparable trend was not noticed in the trial conducted by Guillevin and colleagues.[369] A prospective, randomized trial by Stegmayr and coworkers[362] compared TPE with immunoadsorption. Among 38 patients with non-GPS RPGN, 87% of whom had ANCA, 70% avoided long-term dialysis. TPE and immunoadsorption were equally effective. In a more recent study of 22 patients with ANCA-positive RPGN, 12 patients who received prednisone, cyclophosphamide, and plasmapheresis had better outcomes than did 10 patients who received only drug therapy.[370] Criteria used for treatment-arm assignment were not specified. Thus TPE continues to be controversial in non-GPS RPGN. It is probably not justified as a first-line therapy, except (paradoxically) in patients who initially have dialysis dependence,[371] but it may be offered to patients who progress despite immunosuppressive drug therapy.

Solid Organ Transplantation

TPE has been used in the organ transplant setting both to treat and to prevent rejection as well as to treat recurrence of certain diseases in a transplanted organ. Photopheresis has also been tried for the same purposes, mostly in heart transplantation.

Rejection

Cellular immunity is thought to mediate rejection of most organ allografts; however, rapid antibody-mediated rejection may occur in patients who have preexisting antibodies to ABO or human leukocyte antigen (HLA) expressed by the graft.[372] Histologically, such hyperacute rejection is characterized by fibrin deposition, endothelial damage, and neutrophil infiltration in small blood vessels; damage to the graft parenchyma is mainly ischemic.[373] All treatments, including TPE, have been futile in hyperacute rejection. Vascular

changes reminiscent of hyperacute rejection may be seen in later rejection episodes. These have sometimes been taken to indicate antibody-mediated rejection, even when immunofluorescence microscopy for immunoglobulin and tests for circulating antibody are negative.[373]

Prophylactic immunosuppression with corticosteroids and either cyclosporine or tacrolimus is standard post-transplantation management for kidney and liver transplantation. Heart recipients may also receive azathioprine or mycophenolate mofetil. Rejection episodes occurring in spite of these measures are treated with pulse steroids and/or therapeutic antibodies that deplete T cells, B cells, or both.[374,375]

TPE was used extensively in the late 1970s and early 1980s to treat renal transplant rejection after a number of case reports and uncontrolled series suggested it was beneficial.[376–381] In the middle and late 1980s, however, five controlled trials were reported. Four showed no significant benefit for patients receiving TPE in addition to standard drug therapy, even in the subgroups with vascular histology in transplant biopsies.[382–385] In the single study suggesting benefit, the mean time of treatment was 10 to 11 months after transplantation, when antibody-mediated rejection has been considered less likely.[386] The last and largest study was reported by Blake and colleagues,[385] who concluded that TPE therapy could no longer be recommended for this purpose. All of the aforementioned studies enrolled patients based on the timing of rejection (i.e., early rejection) and/or routine histologic criteria (i.e., acute rejection; vascular rejection). In none of them were patients assessed for the presence of donor-specific antibodies (DSAs). Despite this discouraging experience, use of TPE for renal transplant rejection continued to be reported.[387–389]

In the recent past, a new wave of enthusiasm for TPE has focused on patients with clinical and histologic evidence of acute rejection who also have DSAs and/or deposition of complement component C4d in transplant biopsy tissue.[390–394] DSAs can be shown by a positive crossmatch with donor cells or by flow-cytometric reactions with donor antigens. C4d deposition is demonstrated by immunofluorescence microscopy.[393]

Uncontrolled studies have been encouraging. Observations in the pretransplant period have shown that titers of donor specific HLA and/or ABO antibodies can be reduced by TPE.[219,395] Furthermore, in open trials, patients with refractory acute rejection who demonstrate DSAs and/or C4d have had relatively good long-term graft survival (>80%) after treatment regimens that include TPE and IVIG.[392,393] A recent conference on antibody-mediated rejection recommended that demonstration of circulating DSA be considered an essential criterion for diagnosis of humoral rejection and that the effectiveness of TPE and IVIG in this entity be studied in "rigorous prospective, multicenter" trials.[396]

Notwithstanding its ineffectiveness in controlled trials in renal transplantation, preliminary experience with TPE has also been reported in the context of cardiac allograft rejection. Favorable courses have been seen in individual patients who were also receiving other therapies, but no controlled trials have been reported.[397,398] The criteria for a diagnosis of humoral rejection in this setting remain controversial.[372] Vascular histology is more difficult to detect or exclude in the endomyocardial biopsies done to monitor cardiac allografts because few blood vessels are found in this part of the heart muscle. Immunofluorescence microscopy positive for IgG is the usual criterion for humoral rejection; however, it has been suggested that this diagnosis be made, and TPE used, in patients who have relatively normal biopsies in the context of deteriorating cardiac function.[399] Controlled data to support this assertion are lacking, as are any published data correlating this clinical syndrome with circulating DSAs.

TPE has been used before transplantation in patients presensitized to HLA antigens. Patients whose sera react with lymphocytes from a large proportion of the population have a diminished chance of a compatible crossmatch with an available donor and hence a low likelihood of receiving a transplant. Prospective immunosuppression, combined with removal of antibody by TPE or protein A–Sepharose immunoadsorption, has been tried as a means to obtain a compatible crossmatch and prevent hyperacute rejection. Several groups have reported that patients prepared in this way who receive cadaveric kidney transplants have quite respectable graft survival rates.[400–407] Similar protocols have facilitated successful transplantation of ABO-incompatible kidneys and livers.[217,408–412] In more recent studies, pretransplant TPE has facilitated elective living-donor transplantation of HLA-crossmatch positive as well as ABO-incompatible organs.[220,395,413,414]

In summary, the preponderance of evidence from controlled trials shows that TPE is not effective in reversing established rejection of renal allografts, except possibly in patients with circulating DSAs. Pretransplantation antibody removal can allow transplantation for otherwise ineligible candidates, especially those with high-titer antibodies to one or two HLA antigens whose titer-sensitive crossreactions can be suppressed. It can also facilitate transplantation of kidneys from living donors across ABO and donor-specific crossmatch barriers. The role of TPE in cardiac transplantation, if any, remains unclear.

Recurrence of Disease

Focal glomerulosclerosis (FGS) is a disease that causes nephrosis and renal failure, predominantly in children. It recurs after transplantation in at least 30% of patients who receive an allograft for FGS, suggesting that a humoral factor may play a role in pathogenesis.[415] Some evidence implicates a plasma factor having a molecular mass of 30 to 50 kDa that binds to protein A, is heat sensitive, and is soluble in 70% ammonium sulfate.[416,417] Other factors having estimated masses of 12 to 100 kDa have also been described in some patients.[418] All remain poorly characterized as to structure and half-life. Several reports describe reductions in proteinuria and improved renal function when recurrence of FGS is treated with stepped-up immunosuppression and TPE,[415,419–423] but no prospective randomized controlled studies have been reported.

GPS may occasionally recur in an allograft,[424] although this can usually be avoided by delaying renal transplantation until anti-GBM titers have decreased spontaneously. If it recurs, it should be treated promptly with TPE and cyclophosphamide.

A diffuse coronary artery disease, termed allograft vasculopathy, sometimes develops in transplanted hearts. It is a leading cause of morbidity and mortality in allograft recipients who survive beyond 1 year. It may be related to continuing hyperlipidemia as well as chronic immune injury.[425] Selective depletion of LDLs, discussed in more detail in the following section on hypercholesterolemia, has been thought to be helpful in a few transplant patients with persistent lipoprotein abnormalities.[426] Photopheresis has also been used

as an antirejection measure in this setting (see chapter 56 on cytapheresis).[427]

THERAPEUTIC PLASMA EXCHANGE IN TOXIC AND METABOLIC DISORDERS

This section covers several conditions in which removal of nonantibody substances present in plasma has been deemed therapeutically attractive or advisable. These are listed in Table 55–9, along with the indication categories assigned to them by ASFA and AABB.[40,41]

Hypercholesterolemia

Familial hypercholesterolemia (FH) is an inherited disorder characterized by highly elevated levels of circulating LDL, cholesterol (650 to 1000 mg/dL), and lipoprotein (a) (Lpa). In homozygotes, cholesterol deposits in the form of skin xanthomas and coronary atheromas develop in the first decade of life, and death from myocardial infarction before age 20 years is common. Heterozygotes also have elevated LDL, cholesterol (350 to 500 mg/dL), and Lpa levels; xanthomas may develop by age 20 years, and coronary atherosclerosis, by age 30 years. A genetically determined deficiency of cell surface LDL receptors in these patients interferes with cholesterol off-loading from LDL into cells and with the normal negative-feedback regulation of LDL synthesis, leading to the elevations in LDL and cholesterol.[428,429]

Less severe forms of hypercholesterolemia can be influenced by dietary modifications and are amenable to therapy with several categories of drugs, including 3-hydroxy-3-methylglutaryl coenzyme A reductase inhibitors, bile acid–binding resins, nicotinic acid, and ezetimibe, a new agent that inhibits gut absorption of both dietary and biliary cholesterol.[429] However, FH homozygotes and some FH heterozygotes respond poorly to these measures and remain at high risk for premature death. For such patients, repeated physical removal of LDL and its associated cholesterol can be accomplished by various modalities of therapeutic apheresis.

A 1-plasma-volume TPE lowers LDL and cholesterol levels by 50% or more, and long-term treatment every 1 to 2 weeks can bring about shrinkage of cutaneous xanthomas and regression of coronary deposits.[430–433] TPE removes both LDL and Lpa, but it also depletes high-density lipoproteins (HDLs), which are thought to have a salutary antiatherogenic action. This apparent disadvantage has engendered efforts to remove LDL semiselectively and on-line from patient plasma separated by an apheresis device and then return the LDL-depleted plasma to the patient.

Several systems that have been designed to accomplish this goal are listed in Table 55–10. Secondary filtration systems use a plasma filter with a pore size that retains the very large LDL molecule while sieving smaller ones such as albumin[434]; however, these systems typically remove about half of plasma HDL.[435] In a heparin extracorporeal LDL precipitation (HELP) system, LDL precipitated by heparin at acid pH is removed by filtration from patient plasma that is then dialyzed on-line to restore a physiologic pH.[39,436] Lpa is also depleted, and HDL levels decline by 15%.[435] LDL immunoadsorption columns contain an LDL-specific antibody linked to Sepharose particles.[437,438] The need to reuse columns to achieve cost effectiveness is an awkward feature of this technology.[435] A final system, the Kaneka Liposorber, uses a pair of regenerable dextran sulfate columns that absorb LDL but not HDL or Lpa.[38,439] All these systems remove LDL effectively, but only the dextran sulfate and HELP systems are FDA approved and commercially available in the United States. FDA eligibility guidelines for these devices specify the following minimum LDL cholesterol levels on maximal drug therapy: more than 500 mg/dL for homozygous FH; more than 300 mg/dL for heterozygous FH; and more than 200 mg/dL for heterozygous FH with documented coronary artery disease.[440] Although these systems reduce HDL considerably less than TPE for a given decrement in LDL, they have no application other than the treatment of hypercholesterolemia. Consequently, a center acquiring one of them must use it regularly on multiple patients to make it economically feasible.

Refsum Disease

Refsum disease is an inherited disorder caused by deficiency of the peroxisomal enzyme phytanoyl-CoA hydroxylase, which participates in the normal degradation of phytanic acid by α-oxidation. Symptoms usually begin in the third decade of life as a result of accumulation of diet-derived phytanic acid in plasma lipoproteins and in tissue lipid stores. Peripheral neuropathy, cerebellar ataxia, and retinitis pigmentosa are found in almost all cases. Anosmia, deafness, ichthyosis, renal failure, and arrhythmias may also occur. Slow progression is the usual course, but abrupt deterioration, including sudden death, may follow a marked increase in plasma phytanic acid levels.[441]

Early diagnosis is important so that dietary intake of phytanic acid through dairy products, meats, and ruminant fats can be curtailed. Diet is the mainstay of treatment, leading to gradual clearing of phytanate stores by slow ω-oxidation and gradual symptomatic improvement in most patients. Adequate nutrition must be maintained, however, because overly rapid

Table 55–9 ASFA/AABB Indication Categories for Therapeutic Plasma Exchange in Metabolic Disorders

Disease	Indication Category*

HELP, heparin extracorporeal low-density lipoprotein precipitation; LDL, low-density lipoprotein.

catabolism of endogenous fat can increase plasma phytanic acid levels acutely and cause clinical exacerbations.[441]

TPE has been reported in a number of cases of Refsum disease and removes large quantities of phytanic acid incorporated into plasma lipids.[442] Selective lipoprotein depletion is also effective.[443] Apheresis is probably most appropriate for patients who have very high plasma phytanate levels, particularly those with exacerbation of symptoms. Skin disease, neuropathic symptoms, and ataxia usually improve as plasma levels decrease. Cranial nerve defects usually do not.[441]

Drug Overdose and Poisoning

Toxic effects may arise from intentional or inadvertent exposure to excessive doses of pharmacologic agents as well as from harmful agents encountered in the environment. Management techniques are similar for both types of events and include attempts to remove toxin still in the gastrointestinal tract, efforts to promote or enhance renal elimination, and direct removal from the blood by hemodialysis, hemoperfusion (e.g., over charcoal columns), or TPE.[444] If available, specific antidotes may also be given.[445] Most patients are treated with more than one modality.

TPE has been tried in a number of patients with drug overdose or poisoning. It has been reported to be beneficial, when used along with other therapies, in cases involving substances that bind tightly to plasma proteins.[446,447] Examples include methylparathion,[448] vincristine,[449] vinblastine,[450] cisplatin,[451] carbamazipine,[452] and digoxin bound to antidigoxin Fab fragments.[453] It has also been reported for severe hyperthyroidism, either endogenous or exogenous, although its effectiveness is limited by extensive binding of L-thyroxine to tissue proteins.[454] TPE has been used in several cases of poisoning caused by ingestion of the *Amanita phalloides* mushroom[455,456]; however, diuresis has been shown to clear far more *Amanita* toxin.[457]

Most of the literature on this topic is older and all of it is anecdotal. Furthermore, TPE has always been used in combination with other, presumably effective therapies, making it difficult to formulate firm, rational guidelines. Nevertheless, it seems reasonable to offer TPE to severely affected patients with poisoning or overdose who have high blood levels of an agent known to bind to plasma proteins. Conversely, TPE has shown minimal or no beneficial effect in overdose of drugs known to bind to tissue proteins and lipids, including barbiturates,[458] chlordecone,[459] aluminum,[460] tricyclic antidepressauts,[461] benzodiazepines,[458] quinine,[462] phenytoin,[463] digoxin, digitoxin,[464] prednisone, prednisolone,[465] tobramycin,[466] and propranolol.[467]

Acute Hepatic Failure

Acute hepatic failure (AHF) is an uncommon condition that arises from a severe liver insult. Hepatitis B and acetaminophen overdosage are important causes. Additional cases are due to drug reactions, Wilson disease, vascular anomalies, acute fatty liver of pregnancy, and a variety of toxins. AHF results in myriad metabolic imbalances and synthetic defects. Clinical symptoms include jaundice, coagulopathy, renal failure, and encephalopathy. Liver transplantation is the treatment of choice, leading to 60% to 80% long-term survival versus greater than 60% mortality for patients without transplantation. Many fatal outcomes are due to complications of cerebral edema.[468–470]

Conservative therapy is essentially supportive. Fluid, electrolyte, and nutritional supplements are adjusted to correct metabolic abnormalities. Bowel sterilization with enteral antibiotics is recommended to minimize ammonia production by intestinal flora. Pressors are given as needed for hemodynamic support, and plasma products are infused to combat coagulopathy. Osmotic diuretics, sedatives, hyperventilation, and proper positioning are all used to reduce intracranial pressure.[468–470]

TPE with plasma replacement has inherent appeal as a strategy to restore metabolic homeostasis, remove toxic metabolites that may cause cerebral edema, and supply deficient plasma proteins, such as coagulation factors, in quantity without inducing volume overload. However, evaluations of the effectiveness of this approach have been mixed.[469] Some investigators have thought that TPE is helpful in stabilizing patients and maintaining them until an organ became available for transplantation.[471] Improvements in neurologic status, blood pressure, and cerebral blood flow were attributed to exchanges in one study[472]; however, intracranial pressure, which is a key prognostic indicator, did not decrease. Hemoperfusion over activated charcoal, which reduces plasma ammonia levels, has also shown no advantage over intensive supportive care alone.[470]

Potential problems with extensive TPE arise from the diminished ability of patients with AHF to metabolize the citrate in infused plasma. Citrate accumulation leads to ionized hypocalcemia and to alterations in arterial ketone body ratios that may interfere with regeneration of hepatocytes.[473] Thus although TPE can partially reverse coagulopathy and other synthetic deficits in these patients, a favorable net impact on outcome has been difficult to demonstrate, and it is seldom used for this indication in the United States.[474]

Other methods for extracorporeal support of patients with liver failure have been investigated. Several devices place patient plasma in "metabolic contact" with hepatocyte suspensions of either human or porcine origin. It is proposed that such devices could provide both detoxification and synthetic functions; however, evidence for the latter has been disappointing. Other devices aim to remove toxins via binding to extracorporeal albumin molecules. None of these approaches has yet been shown to improve outcomes for acute liver failure patients in a large controlled trial, but research is ongoing.[474,475]

CONCLUSION

It can be seen from the foregoing that TPE is an effective therapy for a number of disorders, especially those mediated by autoreactive antibodies or paraproteins. Refinements in instrumentation that are outside the scope of this chapter have made it a safe therapy as well; thus it should play an important role in the treatment of selected diseases for the foreseeable future.

Chapter 56

Therapeutic Cytapheresis

Bruce C. McLeod

INTRODUCTION

This chapter will cover apheresis procedures performed on patients to modify or remove excess or abnormal formed elements. Because leukocytes and platelets occupy only a small fraction of total blood volume, they can generally be collected or depleted without a need for volume replacement. Red cells, by contrast, occupy a major fraction of total blood volume. In addition, their presence in the blood in adequate quantities is essential for respiratory gas transport. For these reasons, therapeutic manipulation of the red cell content of blood most often takes the form of an exchange procedure in which patient red cells are removed and simultaneously replaced with normal donor cells.

THERAPEUTIC CYTAPHERESIS

Cytapheresis procedures deplete or collect a component of the buffy coat having a density intermediate between red cells and plasma (Table 56–1). These procedures were the original goal for which centrifugal apheresis instruments were designed, which is why these instruments are sometimes called "blood cell separators."

It is possible for procedures to emphasize collection of either platelets or mononuclear white blood cells (MNCs) depending on centrifugal force, separation-chamber geometry, and, for intermittent collection techniques, the timing of collection events. Addition of an agent such as hydroxyethyl starch to blood entering the centrifuge will promote rouleaux formation, which will accelerate red cell sedimentation in the centrifuge. This enhances the separation between red cells and granulocytes (polymorphonuclear leukocytes; PMNs) (whose density is higher than that of MNCs and overlaps that of the youngest red cells) and thereby enables efficient collection of PMN by an apheresis instrument.[1,2]

Strictly speaking, the term *therapeutic cytapheresis* might be reserved for procedures designed to deplete an abnormal and/or overabundant buffy-coat component. This chapter will have a somewhat larger scope and will include other cytapheresis procedures performed on patients, even though some of them could equally well be considered autologous donations because the expected benefit is not realized until the collected cells are reinfused at a later time. Examples of the latter type of procedure would include collection and infusion of peripheral blood progenitor cells to restore hematopoiesis and collection and subsequent reinfusion of cells that have undergone ex vivo immunization or genetic alteration intended to enhance host immunity or correct a genetic defect.

The extent of reduction in the concentration of a targeted cell in blood by therapeutic cytapheresis is not easily predicted. Formulas based on blood volume, initial cell concentration, and volume of blood processed may give unreliable estimates for several reasons, including (1) the blood volume of patients with elevated cell counts is sometimes underestimated by standard nomograms, (2) more cells can be released into the circulation during a procedure from bone marrow or an enlarged spleen, and (3) the behavior of abnormal cells in a centrifugal field may differ from expectations[2] (Table 56–2) Therefore, rather than prescribe in advance a specific volume to be processed for a therapeutic cell-depletion procedure, it is more reasonable to monitor the cell count of interest during a procedure and, if possible, continue until a meaningful reduction (e.g., 30% to 50%) has been achieved.

Therapeutic Plateletpheresis

An elevated platelet count may be found in three settings: (1) rare familial cases may be due to excessive production of thrombopoietin; (2) a reactive thrombocytosis can occur after several types of inciting events including splenectomy, iron deficiency, malignancy, and chronic inflammation; and (3) finally, a supernormal platelet count may be seen in clonal myeloproliferative disorders such as chronic myelogenous leukemia. When a high platelet count is the only sign of an abnormal clone, the disorder is called essential thrombocythemia. Symptoms attributable to thrombocytosis are seen only in patients who have a myeloproliferative disorder.[3,4]

Rationale

Many patients with thrombocytosis remain asymptomatic indefinitely; however, both thrombosis and hemorrhage are noted with increased frequency in the context of a myeloproliferative disorder. Clotting may be venous (e.g., deep vein thrombosis, Budd-Chiari syndrome) or arterial (e.g., erythromelalgia, stroke). Hemorrhage may be caused by a platelet-function defect or by aspirin given to protect against thrombosis. An age exceeding 60 years, a preexisting cardiovascular disease, or a prior history of thrombosis (or a combination of these) all confer an increased risk for clinical events, the magnitude of which correlates roughly with platelet count (Table 56–3). In younger patients without cardiovascular disease, the risk of clinical events seems unrelated to platelet count (i.e., symptoms may develop with a platelet count of 500,000/μL in some patients, whereas others may remain problem free for years with platelet counts exceeding 1 million/μL).[3,4]

Table 56–1 Density of Plasma and Formed Elements

Component	Specific Gravity
Plasma	1.025–1.029
Platelets	1.040
Lymphocytes	1.050–1.061
Monocytes	1.065–1.070
Granulocytes	1.087–1.092
Erythrocytes	1.093–1.096

Clinical Studies

Little definitive evidence guides therapy for thrombocytosis. A single trial in high-risk patients revealed a reduced incidence of clinical events when the platelet count was kept below 600,000/μL,[5] but no comparable data exist for lower-risk patients. Drug therapy with hydroxyurea or anagrelide will reduce the platelet count of most patients. Therapeutic plateletpheresis is usually reserved for patients with acute, serious thrombotic or hemorrhagic events, or for higher-risk patients with very high platelet counts. When it occurs in such circumstances, thrombocytosis has been rated a category I (standard practice) indication for therapeutic plateletpheresis by the American Society for Apheresis (ASFA)[6] and AABB[7] (Table 56–4). An urgent plateletpheresis will reduce the platelet count promptly, and additional procedures can maintain a reduced level until drug therapy takes effect.[2,3]

Technique

Therapeutic plateletpheresis can be performed with any centrifugal apheresis instrument. Procedural variables such as anticoagulation, centrifuge speed, and separatory chamber configuration are usually the same as those used for a platelet donation; however, it may be desirable to maintain a higher flow rate in the component-removal line in an instrument so equipped.[2] As mentioned, the platelet count decrement for a single procedure cannot be reliably predicted on the basis of the volume of blood processed. Monitoring intraprocedural platelet counts is the best way to ensure that the desired decrement (e.g., a 50% decline) is obtained before a procedure is discontinued.

Therapeutic Leukapheresis

The great majority of therapeutic leukapheresis procedures are carried out to treat hyperleukocytosis occurring in association with leukemia, but a few other indications should be briefly mentioned. Depletion of nonmalignant lymphocytes by apheresis, with or without simultaneous therapeutic plasma exchange (TPE), has been reported in several autoimmune disorders. Rheumatoid arthritis,[8] progressive multiple sclerosis,[9] inclusion body myositis,[10] polymyositis, and dermatomyositis[11] have all been assigned indication categories by ASFA[6] and AABB[7] (see Table 56–4); however, leukapheresis to deplete nonmalignant lymphocytes has not become an accepted treatment for any autoimmune disorder. Leukapheresis has been used to remove malignant lymphocytes from patients who have Sézary syndrome in the context of cutaneous T-cell lymphoma (CTCL)[12,13]; this is also a category III indication (see Table 56–4).[6,7] However, it has been largely replaced by photopheresis, as discussed later.

2. Cardiovascular disease
3. History of thrombosis

Rationale

The clinical manifestations associated with a highly elevated white blood cell (WBC) count (hyperleukocytosis) in leukemia patients include leukostasis, tumor lysis syndrome, and early mortality. These are not mutually exclusive, and it is therefore useful to keep all of them in mind when considering the potential for benefit from therapeutic leukapheresis.

Leukostasis is diagnosed when evidence is present of organ dysfunction due to microvascular obstruction and consequent patchy ischemia. Neurologic and pulmonary dysfunction are the most common examples in acute leukemia; priapism is another possible complication in patients with chronic myelogenous leukemia (CML).[14,15] The pathologic basis for these symptoms is believed to be small-vessel occlusion by masses of leukemic cells, possibly with thrombosis, and sometimes with hemorrhage distal to the occlusion.[16,17] Such obstructions have been attributed to rheologic consequences of an increased blood concentration of WBCs,

Table 56–4 ASFA/AABB Indication Categories for Therapeutic Cell Depletion

Disease	Procedure	Category
Thrombocytosis	Plateletpheresis	I
Hyperleukocytosis	Leukapheresis	I
Rheumatoid arthritis	Lymphoplasmapheresis	II
Progressive multiple sclerosis	Leukapheresis	III
Inclusion body myositis	Leukapheresis	IV
Polymyositis	Leukapheresis	IV
Dermatomyositis	Leukapheresis	IV
Heart transplant rejection	Photopheresis	III
Cutaneous T-cell lymphoma	Photopheresis Leukapheresis	I III
Sickle cell disease	Red cell exchange	I
Severe malaria/ babesiosis	Red cell exchange	III

I, standard therapy; II, evidence suggests efficacy; III, inadequately tested; IV, ineffective in controlled trials.

especially increased viscosity.[18] However, concomitant anemia keeps the whole blood viscosity within the normal range in most patients with leukemia,[19,20] unless ill-advised red cell transfusions are given before the WBC count has been lowered.[21] More recent studies have identified reduced deformability, cytokine secretion, and altered adherence properties of blasts or other primitive cells as factors contributing to leukostasis.[2,22,23] These factors could explain not only why leukostasis correlates more closely with the circulating blast count than with total WBC count, but also why the absolute blast count at which symptoms occur can vary widely from patient to patient.[24,25]

Leukostasis occurs in about 5% of patients with acute myelogenous leukemia (AML).[14] Autopsy studies have shown microscopic evidence of leukostasis in most AML nonsurvivors whose WBC counts exceeded 200,000/μL.[17] The blast count exceeds 100,000/μL in most clinically evident instances of leukostasis; however, the syndrome is occasionally suspected in patients when the blast count is only in the 50,000 to 100,000/μL range.[26] Leukostasis is seldom seen in acute lymphocytic leukemia, and then only when the WBC count reaches the 250,000 to 300,000/μL range.[24] Higher cell counts, usually in the 300,000 to 500,000/μL range, are required before the more mature cells that circulate in CML can cause signs of leukostasis,[15] whereas counts above even this level may be tolerated without symptoms in chronic lymphocytic leukemia.[2]

Even in patients who do not have leukostasis, hyperleukocytosis is a marker for a poorer prognosis in both acute and chronic leukemias. Both short-term and long-term survival are inversely correlated with presenting WBC count, as are the complete remission rate and the mean duration of response to chemotherapy.[27] Finally, hyperleukocytosis is associated with a higher incidence of hyperuricemia and other manifestations of tumor lysis syndrome, all of which may be exacerbated by cytotoxic chemotherapy.[28]

Clinical Studies

It is widely accepted, based on accumulated clinical experience rather than controlled studies, that reducing the WBC count by leukapheresis can reverse symptoms of leukostasis, although it may not do so if tissue infarction as well as ischemia has occurred. This is the basis for the ASFA/AABB ranking of hyperleukocytosis as a category I indication for leukapheresis (see Table 56–4).[6,7] Leukapheresis should be carried out as an emergency in leukemia patients with symptomatic leukostasis, especially acute leukemia patients with blast counts exceeding 100,000/μL. Wide acceptance of this principle led to the question of whether urgent prophylactic leukapheresis might be prudent in acute leukemia patients with WBC or blast counts exceeding 100,000/μL, even if they do not have signs of leukostasis. Evidence for benefit from such prophylactic leukapheresis is limited, and this practice remains controversial; nevertheless, urgent leukapheresis may be requested routinely on this basis by individual physicians or as institutional policy, and requests for repeated leukapheresis may be made when acute leukemia patients' WBC counts remain high for several days before chemotherapy is instituted.[24,25] An extreme example of the latter was a pregnant patient who received only leukapheresis therapy for several weeks after a diagnosis of acute leukemia was made because she wished to delay chemotherapy until after delivery.[29]

It is still not clear that reducing the WBC count by leukapheresis before initiation of chemotherapy prevents or meaningfully reduces the severity of tumor lysis syndrome. A counter-argument to the prediction of such benefit is that the leukemic cells accessible for removal from the circulation represent only a small fraction of the total tumor burden and that a meaningful reduction in tumor load is not likely to be achieved in this way. Controlled studies that address this point have not been reported. It is also unclear whether prophylactic leukapheresis improves survival in patients with hyperleukocytosis, either by attenuating tumor lysis syndrome or in some other way.

Three observational studies of prophylactic leukapheresis have been published in the past decade. One group reported 48 consecutive AML patients who received leukapheresis if the presenting WBC count exceeded 100,000/μL. The extent of WBC count reduction was not significantly different between the 14 patients who died within 2 weeks and the remaining patients, suggesting that WBC count reduction was not an important predictor of mortality.[30] Another nonrandomized, retrospective study of 146 patients with AML and a WBC count exceeding 50,000/μL showed a higher 2-week survival (87% vs 77%) in patients who had leukapheresis; this was statistically significant only in a logistic regression analysis. Follow-up observation, however, showed no advantage in 4-week, 6-week, or overall survival. Paradoxically, long-term survival was significantly lower in the group that had leukapheresis.[31] A third study looked at outcomes in 53 patients with AML and WBC counts exceeding 100,000/μL, all of whom underwent daily leukapheresis (76 procedures total) until the WBC count dropped below 100,000/μL or the performance status improved. Only two patients died in the first week; however, despite the prophylactic WBC removal, 47% developed coagulopathy, 85% developed tumor lysis syndrome that was severe in 53%, and only 55% achieved a complete remission. Median survival among the responders was only 8 months.[32]

Taken as a whole, these reports provide little indication of benefit from routine prophylactic leukapheresis in hyperleukocytic AML patients. Indeed, the results might equally well imply that hyperleukocytosis is merely a marker for other risk factors, such as morphologic category, specific chromosomal abnormalities, and/or total tumor burden, that cannot be altered simply by leukapheresis. Prospective randomized controlled studies are needed before routine prophylactic leukapheresis can be recommended.

Technique

Therapeutic leukapheresis can be accomplished with most centrifugal apheresis instruments. Urgent treatment of patients with inadequate peripheral venous access may require equally urgent placement of a dual-lumen central venous catheter, which can be challenging in acutely ill patients with the low platelet counts that often occur in leukemia. When contemplating leukapheresis in a patient who does not have leukostasis, the unproven benefits of treatment should be balanced against the potential hazards of emergency central-line placement and delay in starting pharmacologic cytoreduction with hydroxyurea and definitive chemotherapy.[24,25]

Cell removal will be more efficient in most instances if hydroxyethyl starch or another sedimenting agent is added to patient blood before it enters the centrifuge. Also, removal of leukemic cells, even in a concentrate containing 500,000 to 750,000 leukocytes per microliter, may entail large plasma losses. The volume-expanding properties of a sedimenting

agent can offset this to some extent, but additional colloid replacement is wise if the volume of leukocyte concentrate removed exceeds 1 L.[2]

The extent to which the WBC count must be reduced to prevent or reverse leukostasis cannot be known in advance for an individual patient with any degree of certainty. Nevertheless, it is reasonable to expect clinical improvement in a patient with leukostasis if the WBC count is promptly reduced by 30% to 50%, ideally to less than 100,000/μL in AML or less than 300,000/μL in CML. The extent of prophylactic leukocyte removal that might be needed to prevent tumor lysis syndrome or improve survival is even more uncertain. As mentioned previously, it is difficult to predict WBC count reduction merely on the basis of the volume of blood processed.[2] It is therefore worthwhile to monitor intraprocedural WBC counts to assure that a targeted reduction is reached.

Photopheresis

In an extracorporeal photochemotherapy (ECP or photopheresis) treatment, patient MNCs separated by leukapheresis are exposed to a standardized dose of ultraviolet A radiation (UVA) in the presence of 8-methoxypsoralen (8-MOP) at a concentration of 60 to 200 ng/μL. 8-MOP is a photoactive compound that will crosslink nuclear DNA in the treated cells by means of diadducts between proximate thymidine residues in complementary strands. Protein changes may occur as well. After a short incubation, the irradiated cells are returned to the patient. Although conceptually independent, the modules performing the apheresis and irradiation steps can be housed in a single instrument such as the UVAR XTS system (Therakos, Exton, Pa.). 8-MOP was originally given orally shortly before apheresis but is now available in a preparation suitable for intravenous administration that can be added to the MNC concentrate after collection but before UVA irradiation. This provides much better control of 8-MOP concentration during irradiation; in addition, it reduces the dose of 8-MOP given to the patient by a hundredfold, thereby reducing side effects such as photosensitivity. In most of the applications to be discussed, ECP has usually been performed on one or two consecutive days at 2- to 4-week intervals.[33]

Cutaneous T-Cell Lymphoma

ECP was devised in the 1980s as a therapy for CTCL, a disease in which malignant lymphocytes are typically abundant in the bloodstream as well as in skin infiltrates.[34] Certain cutaneous manifestations of CTCL were known to improve after depletion of malignant cells by leukapheresis[12,13] and also after UVA irradiation of skin after ingestion of 8-MOP (psoralen-UVA treatment; PUVA).[35] Collection, UVA irradiation and reinfusion of 5% to 10% of circulating MNCs on 2 consecutive days monthly led, after a delay of some months, to dramatic improvement in some patients. Responses of the magnitude observed cannot be accounted for simply by destruction of UVA-irradiated tumor cells, and this quantitative discrepancy suggested the possibility that ECP may elicit, enhance, or otherwise modulate a host immune response to the tumor.[23,24] This hypothesis provides a theoretical framework for trials of ECP in other diseases in which immunomodulation seems a reasonable approach to therapy.

Nine North American studies have reported 282 CTCL patients who received ECP.[34,36–43] Of these, 18% had a complete response, and another 38% had a partial response.[44] Long-term follow-up suggested better median survival than had been observed in historic controls. ECP seems most active in patients who have had relatively recent onset of diffuse skin disease (erythroderma) but still have relatively little of the immunosuppression that often accompanies advanced disease. Results are not as good in patients with localized skin plaques, long-standing disease, and/or involvement of lymph nodes and viscera.[44,45]

The FDA approved Therakos's original UVAR system for treatment of CTCL in 1987, and this use has been rated a category I indication for ECP by ASFA[6] and AABB[7] (see Table 56-4). Unfortunately, although its ability to produce regression of erythroderma is well established, the optimal role of ECP in CTCL remains uncertain because, unlike almost all drug therapies for malignant disease, it has never been subjected to controlled trials with uniform enrollment and response criteria comparing it with no treatment, sham ECP, or alternative therapies.[46]

Graft versus Host Disease (GVHD)

GVHD is most often encountered as a complication of allogeneic stem cell transplantation. It affects skin, liver, and gastrointestinal (GI) tract. Acute GVHD begins before day 100 after transplant and is mostly inflammatory, whereas chronic GVHD begins after day 100 and may include scleroderma-like skin thickening and other fibrotic changes. Both forms occur frequently in allograft recipients despite prophylaxis with corticosteroids and other immunosuppressive drugs. Each form has about a 30% incidence after HLA-matched sibling transplants; after partially mismatched related or matched unrelated transplants, the respective incidences are in the 50% to 80% range.[33,47]

Skin GVHD sometimes improves after PUVA therapy.[48] ECP was tried in hopes of addressing visceral involvement via a similar mechanism and has been reported to be beneficial in both acute and chronic GVHD. In both settings, the best responses are noted in skin manifestations.[33,49] Eleven reports on acute GVHD,[47,50–59] including observations of 76 patients, have been analyzed.[47] Of the patients with skin disease, 83% showed improvement after ECP, with a complete response recorded in 67%. Complete regression was also observed in 54% of cases with GI involvement and 38% of cases with liver disease. Twenty reports on chronic GVHD[47,52–54,56,59,60–72] also have been analyzed.[47] Of 160 patients with skin disease, 76% improved after ECP, with a complete response being noted in 35%. Improvement was also reported in 48% of 84 patients with liver involvement, 39% of 31 patients with lung disease, and 63% of 59 patients with oral manifestations. Responses in this context are said to be quicker than those seen in CTCL, with improvement evident in a matter of weeks. Survival is also thought to be improved.[47] Again, however, the precise contribution of ECP to treatment of GVHD must be regarded as uncertain because ECP-treated patients generally receive other therapies concomitantly, and no prospective controlled trials have been reported. GVHD has not been rated as an indication for ECP by either ASFA or AABB.

Solid Organ Transplant Rejection

Immunomodulation by means of ECP has also been undertaken in patients who are rejecting a solid organ transplant. A number of case studies and small series have described recipients of kidney[73–75] and lung[76–80] allografts who improved

when ECP was added to a conventional antirejection regimen. The largest experience, however, has come from heart transplantation.

In considering the use of ECP in heart transplantation, it is important to point out that the term *rejection* has a subtle additional connotation in that context that does not apply to other organ allografts. Transplanted kidneys and lungs are seldom biopsied unless signs of organ dysfunction are present; however, the low risk and relative simplicity of endomyocardial biopsy (EMB) permits a cardiac allograft to be sampled routinely, often in the absence of cardiac dysfunction. It is also customary for patients who have mild histologic changes in such surveillance biopsies to be treated preemptively and aggressively for rejection in the absence of any signs of cardiac dysfunction.

The first reports of ECP in cardiac allograft recipients described cases with severe, hemodynamically significant rejection who improved after ECP was added to other antirejection therapies.[33,81] Subsequent studies have tended to focus on the more common patients with normal hemodynamics and mild histologic changes on EMB. A controlled trial with eight patients per arm found ECP to be equivalent to high-dose corticosteroids in reversing mild histologic changes on EMB.[82] The significance of this finding is open to question, however, because other studies have suggested that such changes usually resolve without adjustments to antirejection therapy.[83] A controlled trial of prophylactic ECP in 60 patients with cardiac transplants showed a lower incidence of mild histologic changes in patients who received ECP prophylaxis, but no difference in the rate of severe rejection with hemodynamic compromise.[84] Absent controlled trials in patients with severe rejection, the uncertainty about the prognostic significance of mild histologic changes contributes to uncertainty about the proper role for ECP in treatment of rejection of heart and other organ transplants. Heart transplant rejection has been rated as a category III indication for ECP by ASFA[6] and AABB[7] (see Table 56–4).

Autoimmune Diseases

Immunomodulation with ECP has been tried in a number of autoimmune diseases, including scleroderma,[85] systemic lupus erythematosus,[86] pemphigus vulgaris,[87] rheumatoid arthritis,[88] and psoriatic arthritis.[89] Favorable results have been reported in case studies and small series. More extensive experience in scleroderma has indicated limited benefit at most,[90] whereas data from controlled trials of ECP in other autoimmune disorders are still lacking.

Mechanism of Action

The mechanism of action of ECP is not known with certainty for any of the applications mentioned earlier. No doubt exists, however, that it leads to apoptosis in a majority of treated lymphocytes while leaving treated monocytes relatively intact and viable. UVA-induced DNA crosslinking by 8-MOP is probably an important contributor to this effect, although other mechanisms, such as protein damage, may operate as well.

In CTCL, it is supposed that apoptosis of malignant lymphocytes exposes or releases tumor-specific antigens in a more immunogenic fashion, thereby eliciting or enhancing host immune responsiveness to the tumor. Recent studies suggest that contact with plastic surfaces of the disposables in the apheresis instrument and the UVA irradiation apparatus induces collected monocytes to differentiate into dendritic cells. It is theorized that activated dendritic cells then ingest tumor antigens being released from apoptotic cells and facilitate antigen presentation, thus leading to enhanced immunity.[91,92]

A similar mechanism could be envisioned for ECP in other applications; that is, a downregulating response to a pathogenic though nonmalignant lymphocyte clone is enhanced through release of clone-specific antigens by apoptosis, followed by vigorous presentation of these antigens by abundant activated dendritic cells.[49,93] At present, however, this mechanism should be regarded as hypothetical. Circulating clonal lymphocytes have been found in scleroderma[94] and GVHD,[49] but thus far, neither pathogenicity nor downregulation by ECP has been shown for such clones.

The putative effects of ECP in GVHD have also been attributed to more general immunomodulatory effects. One hypothesis involves a shift from an inflammatory Th1 cytokine expression profile to a more inhibitory Th2 profile.[95] A second envisions a paradoxical decrease in dendritic cell function in this context.[96]

Peripheral Blood Progenitor Cell Collection

Autologous MNCs, collected by leukapheresis and cryopreserved, have all but replaced bone marrow as the preferred source of stem and progenitor cells for autologous hematopoietic rescue after myeloablative antitumor therapy for lymphomas, leukemias, myeloma, and other malignancies.[97] A similar approach is being tried in some autoimmune diseases.[98] Stem and progenitor cells do not circulate in the basal state in quantities sufficient for this purpose; however, they can be stimulated to enter the bloodstream in any of several ways. One is to give a "conventional" dose of an appropriate chemotherapeutic agent as "mobilizing chemotherapy" roughly 10 to 14 days before the planned date of collection. When the WBC count begins to increase after the expected interval of leukopenia, the blood concentration of CD34-positive cells, which is a marker for peripheral blood progenitor cell (PBPC) concentration, increases by as much as 25-fold and remains elevated for up to a week.[99,100] A second method is to give daily injections of a hematopoietic growth factor. Both granulocyte colony–stimulating factor (G-CSF; filgrastim; Neupogen)[101,102] and granulocyte-macrophage colony–stimulating factor (GM-CSF; sargramostim; Leukine)[103] injections will induce worthwhile levels of circulating CD34-positive cells in most individuals in 4 to 5 days; these levels will persist for up to a week with continued daily injections. In the autologous setting, G-CSF or GM-CSF or both can be given during recovery from mobilizing chemotherapy for maximal mobilization.[104–106] A number of other cytokines will also mobilize PBPCs, but none is commercially available at this time.[107]

Goals for total CD34-positive cell yield from autologous PBPC collections range from 2×10^6 to 5×10^6 CD34-positive cells per kilogram per transplant at different centers. Most patients will respond to mobilizing stimuli well enough to reach their goal after one to three daily leukapheresis procedures. A smaller proportion with suboptimal mobilization may require four to five daily collections. Perhaps 10% of patients, most of whom are older or have had extensive prior chemotherapy or both, will fail to have a useful response to conventional mobilization strategies. Their blood CD34-positive cell levels (expressed in cells per microliter) will not increase above the low single-digit range, levels at which

daily leukapheresis procedures will seldom produce the target yield within the limited period of mobilization.[107]

PBPCs are preferred over cells from bone marrow harvests for two reasons. The first is that the collection procedure does not require hospitalization or general anesthesia. The second is that WBC and platelet counts recover about a week sooner after PBPC transplantation than after bone marrow transplantation. The resultant reduction in early morbidity and mortality from infection and bleeding more than offsets a somewhat higher incidence of GVHD with PBPC.[97]

Candidates for PBPC collection have unique vascular-access needs. They require a multilumen, tunneled central vein catheter for diagnostic blood draws, transfusion support, fluid maintenance, and chemotherapy infusions during both the pre- and post-transplant periods; however, catheters designed solely for these purposes are too flexible and have a diameter too small to support the flow rates required for efficient leukapheresis. Fortunately, tunneled dual- or triple-lumen apheresis catheters (e.g., Raaf catheter) that accommodate both PBPC collection and the full range of other intravenous-access requirements are now commercially available. Potential autologous PBPC transplant recipients will usually benefit from having such a catheter placed. A notable exception would be a patient having a precautionary collection that would only be used in the event of an unexpected or late relapse. Such "harvest and hold" patients should have leukapheresis via peripheral veins if possible.

PBPC collections are quite prolonged apheresis procedures. It is commonplace for 15 to 30 L of patient blood to be processed in a 4- to 6-hour period. Such extensive procedures may entail enough incidental platelet loss to warrant platelet transfusions for patients who are already somewhat thrombocytopenic. They also entail prolonged infusion of citrate anticoagulant and therefore a large cumulative citrate dose. Conflicting reports concerned the frequency of adverse effects during PBPC collection. A multicenter survey that included both autologous and allogeneic donors but did not track either mild paresthesias or calcium-replacement practices revealed only a 1.33% incidence of spontaneously reported adverse effects in 664 PBPC collections.[108] A later study at a single center found a 54% incidence of symptoms in carefully questioned donors during 71 allogeneic PBPC collections performed without intravenous calcium supplementation. Serum ionized calcium decreased by 20% to 35% during these procedures. Symptoms were especially prevalent in smaller female donors. The same investigators found a 20% incidence of symptoms among 244 donations performed with prophylactic intravenous calcium supplementation, with only a 10% to 15% decrease in ionized serum calcium.[109] Although the latter studies monitored allogeneic donations, they suggest that intravenous calcium supplementation might prevent mild paresthesias during autologous PBPC collections as well, especially those done on smaller female patients.

Autologous Mononuclear White Blood Cells Altered Ex Vivo

Autologous MNCs collected by leukapheresis provide the starting material for a number of established and experimental cellular therapy techniques.

Purification and Expansion

Purification of MNC subsets has been explored in autologous PBPC transplantation. This has been done primarily to address potential tumor cell contamination. In positive selection approaches, stem and progenitor cells are purified from all other MNC, including any contaminating tumor cells. The most prevalent techniques are immunologic ones that target the CD34 antigen. Several of these are commercially available. Stem cells thus purified also provide an attractive starting material for in vitro expansion techniques that could enhance the outcome of transplantation in other ways. An alternative approach to purification is negative selection to deplete tumor cells actively from an MNC concentrate. Sequential positive and negative selection approaches also are possible.[110] Gene-marking experiments identified tumor cells derived from autograft contamination in metastases developing after transplantation[111]; however, to date, no stem cell purification process has been shown to enhance survival after transplantation in any illness.

Immunization

A number of in vitro strategies have been proposed to induce and/or enhance antimicrobial or antitumor immunity expressed by autologous immunocytes present in MNC concentrates. Enhanced antigen presentation, release from inhibitory influences operative in vivo, and/or selective stimulation by supraphysiologic "cytokine cocktails" are potential mechanisms that could facilitate immune responses that could not be achieved in vivo and might result in desirable therapeutic effects after reinfusion of treated cells. Some approaches of this nature have shown promise in melanoma, renal cell carcinoma, and prostate cancer.[112]

Gene Insertion

Autologous hematopoietic stem and progenitor cells collected by leukapheresis are promising targets for therapeutic gene insertion. They can be obtained in abundance with relative ease, and they or their progeny can potentially survive indefinitely after genetic alteration and reinfusion. Encouraging early successes were achieved in correcting immunodeficiency due to adenosine deaminase deficiency, but gene therapy has subsequently proven to be a very challenging endeavor.[113]

RED CELL EXCHANGE

Description of Procedure

The most common manipulation of red cells by apheresis is red cell exchange (RCE), in which patient red cells separated by the instrument are removed while compatible donor red cells are added to patient plasma and reinfused. Two other manipulations are possible. Red cells can be depleted rapidly and isovolemically from patients with polycythemia by removing red cells and adding 5% human serum albumin (HSA) or fresh frozen plasma (FFP) at the same rate to the patient's plasma for reinfusion.[114,115] Alternatively, red cells can be transfused rapidly and isovolemically to anemic patients by removing patient plasma while adding compatible donor cells to the patient's red cells at the same rate to be reinfused.[116]

The kinetics of a "pure" RCE are similar to those of TPE, such that the equation and graph in the previous chapter (see Fig. 55–1) can be used to determine the fraction of patient red cells remaining (FCR) after exchange of a given number of patient red cell volumes. Some apheresis instruments include

programming that accepts operator input for patient height, weight, hematocrit, the desired FCR, and the expected hematocrit of donor PRBCs, and then calculates the volume of packed red cells that should be exchanged.

Outcomes of RCE in some applications can be made more effective and efficient in ways not feasible for TPE. If the patient's baseline hematocrit is not too low (i.e., >24%), isovolemic removal of patient red cells with HSA replacement can be carried out at the beginning of the exchange to an extent that will reduce the hematocrit to the minimum safe level. Because no donor cells are infused, none can be subsequently withdrawn, and removal of patient cells during this preliminary phase is therefore 100% efficient. Similarly, if the hematocrit at the end of an exchange is not too high (i.e., <30%), additional donor red cells can be infused simultaneously with patient plasma removal to increase the hematocrit isovolemically to the desired or maximal safe level. Because no red cells are removed in this phase, provision of normal donor red cells is 100% efficient. A benefit similar to such postexchange red cell transfusion can be achieved during the exchange by withdrawing red cells at a hematocrit lower than that of infused PRBCs, thus raising the hematocrit gradually. Combining these two strategies (that is, pure patient cell removal at the beginning of a procedure and pure infusion of donor cells or gradual raising of hematocrit at the end of the procedure) can make a red cell "exchange" procedure more efficient (i.e., produce a lower FCR) than the formula in Figure 55-1 would predict for the volume of donor red cells used.[117]

Because red cell volume is less than plasma volume, especially in anemic patients, the total volume of blood processed in an RCE procedure tends to be less than that in TPE. Flow rates can also be lower. These factors predict a lower risk for citrate toxicity. Conversely, patients having RCE are at risk for both hemolytic and nonhemolytic reactions to red cell transfusions, and these risks are higher in patients who have had multiple RCE or are multitransfused for other reasons, because such patients have an increased likelihood of becoming alloimmunized to minor red cells antigens that could mediate a hemolytic reaction, as well as to HLA antigens that may be involved in febrile nonhemolytic transfusion reactions. In a multicenter study, the risk of an adverse reaction observed in 78 RCE procedures was 10.3%.[108]

Finally, many RCEs are performed on pediatric patients with sickle cell disease (SCD) whose small body size can make them more susceptible than adults to imprudent levels of hypovolemia or anemia during the procedure. The latter risk can be avoided in younger children by priming the apheresis instrument with 5% HSA and/or donor PRBCs as appropriate.

Sickle Cell Disease

The great majority of RCEs are done for complications of SCD in patients who are homozygous for hemoglobin S (HbS) or have another hemoglobinopathy. Briefly stated, the rationale for removing patient red cells and transfusing normal red cells containing hemoglobin A (HbA) in RCE is to create a hemoglobin mixture similar to that found in sickle trait cells, in which a majority of circulating hemoglobin is HbA. Because HbS-containing cells are less likely to sickle in such cell mixtures, RCE can interrupt the vicious cycle of sickling, stasis, and progressive hypoxia that occurs during sickle cell crisis.[118] The exact proportions of HbA and HbS needed to achieve this are not known with certainty; however, plans for RCE are usually formulated with a goal of increasing HbA above 70% of the total (i.e., FCR <30% in an untransfused patient) so that a HbA level above 50% will persist for several weeks. For some indications discussed later, it is desirable to maintain HbA above 70% for a prolonged interval. In appropriate circumstances, SCD is rated a category I indication for RCE by ASFA[6] and AABB[7] (see Table 56–4).

When transfusing SCD patients, it is important to avoid raising hematocrit much above 30% because at higher hematocrits, blood viscosity reaches levels that can exacerbate the microvascular ischemia that transfusion therapy is intended to combat. RCE is favored over simple transfusion in urgent circumstances because it can increase HbA quickly without a proportionate increase in hematocrit.[119] By contrast, long-term maintenance of a high HbA and low HbS can be achieved and sustained in SCD patients by repeated simple transfusion to a hematocrit of about 30% at 2- to 4-week intervals. Transfused cells survive longer than the patient's own cells and will tend to accumulate on that basis alone. In addition, suppression of erythropoietin synthesis by the higher post-transfusion hematocrit leads to reduced production of patient cells. In a comparison with RCE, the advantages cited for repeated simple transfusion are a lower cost and a reduced number of PRBC units needed per unit of time in a prolonged transfusion program. The advantages cited for RCE are (1) used as an emergency, it can raise HbA to 70% to 90% rapidly (in a few hours rather than a few weeks); (2) treatments are shorter and can be less frequent; and (3) less iron loading occurs with RCE because red cell removal is nearly equal to red cell transfusion.[119–121] This comparison is summarized in Table 56–5. In the present era, when the perceived risk of transfusion-transmitted infection is low, the reduction in iron loading with RCE is often deemed to outweigh the incremental infection risk associated with the greater number of units transfused. This leads many practitioners to favor RCE over simple transfusion as a means for long-term maintenance transfusion therapy.

If RCE is to be done, the number of units to be exchanged must be specified. This will depend on the patient's body size, the goal for post-treatment HbA and HbS levels, and the patient's recent transfusion history. The latter is important because a smaller exchange will suffice to reach a given post-treatment HbA goal if the patient already has some HbA circulating. A patient who has not been transfused for several months can be assumed to have no circulating HbA, whereas a patient in a regular maintenance exchange program might be expected, based on previous measurements,

Table 56–5 **Comparison of Red Cell Exchange and Simple Transfusion for Long-Term Maintenance Transfusion in Hemoglobinopathies**

	Simple Transfusion	Red Cell Exchange
Cost	Lower	Higher
PRBC units required	Fewer	More
Convenience of treatment	Worse	Better
Frequency of treatment	Higher	Lower
Iron overloading	More	LESS

PRBCs, packed red blood cells.

to have a 50% to 70% HbA level before the next exchange. In the absence of a recent hemoglobin electrophoresis, one must make a reasonable, preferably conservative estimate of pretreatment HbA.

Certain special requirements are appropriate for PRBCs to be transfused to SCD patients in either RCE or long-term simple transfusion regimens. Donors should be tested for and found negative for sickle trait, so that all transfused hemoglobin will be HbA. Leukocyte depletion is warranted to avoid febrile transfusion reactions; when these occur, the time required to rule out a hemolytic reaction is especially disruptive during RCE because the procedure must be halted for an hour or more. Some practitioners prefer to provide PRBCs that are phenotypically matched with the recipient to a greater or lesser extent to avoid alloantibody formation.[121] Others are content to deal with antibody workups as they arise and provide antigen-negative PRBCs only to the minority of patients who develop specific antibodies. Finally, some authors consider it important to provide relatively fresh PRBCs to certain patients, such as those with a new stroke or acute chest syndrome, who might have difficulty tolerating a temporary deficit in oxygen delivery associated with transfusion of older blood. None of these requirements should be regarded as absolute, and judgment must be exercised when adherence to any or all of them would delay a procedure in an emergency situation. Thus one might accept some units from donors with sickle trait if they are the only compatible cells available for a patient with a difficult constellation of alloantibodies. One might also waive prophylactic phenotypic matching for a patient with an uncommon phenotype or accept the freshest units available rather than insist on a predefined maximal age for PRBC units.

Stroke

Central nervous system (CNS) infarction is a common and potentially devastating complication of SCD that poses a particular threat to children with the disease.[122] In the United States, the prevalence of overt stroke is 11% by age 20 years in untreated SCD patients; another 17% will have evidence of clinically silent infarcts in CNS imaging studies.[123,124] Furthermore, children who have had one stroke are at high risk for subsequent CNS events. The recurrence rate was 67% in one study of patients with a history of overt stroke,[125] and a 14-fold increase in the risk of overt stroke was found in children with silent infarcts on CNS magnetic resonance imaging (MRI).[126]

Most childhood strokes are due to thrombosis at sites of previous narrowing in cerebral arteries. The presence of predisposing vascular lesions can be inferred from elevated blood-flow velocities detected by transcranial Doppler ultrasonography (TCD).[127] The incidence of stroke in children with abnormal TCDs is 10% to 13% per year versus the baseline risk of 0.5% to 1.0% per year.[128]

Long-term simple transfusion or maintenance RCE regimens designed to keep HbS below 30% have been used empirically to prevent recurrences in children who have had a stroke.[129,130] A randomized study of prophylactic transfusion to maintain HbS at less than 30% in children with abnormal TCDs showed a 90% reduction in the incidence of stroke in the transfused arm over a period of about 2 years. The incidence of new silent infarcts was similarly reduced. Most patients in that arm received simple transfusion. Iron overload requiring chelation therapy was a significant problem but was less severe in the minority of patients who received transfusions via RCE.[128] In another study of children with an abnormal TCD and a silent infarct on MRI, prolonged transfusion reduced the incidence of both overt stroke and new silent infarcts.[131]

Long-term simple transfusion or maintenance RCE to keep HbS less than 30% is recommended for SCD children with abnormal TCDs, overt strokes, or silent infarcts on MRI. Early cessation of transfusion after a primary stroke restores the baseline risk of recurrence.[132,133] In a randomized study performed in children who had received prophylactic transfusion for high-risk TCD findings for 30 to 91 months with correction of TCD velocities to low-risk values, discontinuation of transfusion was followed by reversion to high-risk TCD velocities or by clinical stroke within 4 to 9 months in 16 of 41 patients, versus no such events in patients who continued transfusion.[134] Transfusion becomes less onerous if the HbS goal is relaxed to less than 50% after several years without a CNS event,[135] but the risk of stroke after such an adjustment has not been established and may therefore be increased.[130] It may be reasonable to discontinue transfusion therapy when patients reach age 18 years because the baseline incidence of stroke is lower in young adults with SCD,[136–138] but this too remains unproven.

The incidence of a CNS event increases again in older SCD patients. These are usually hemorrhagic strokes. No conclusive evidence exists that urgent RCE improves short-term outcomes in children or adults with acute strokes, or that either long-term simple transfusion or maintenance RCE reduces the risk of recurrent stroke in adults.[139,140] Nevertheless, these are common practices in some institutions.

Acute Chest Syndrome

Acute chest syndrome (ACS) is an important cause of morbidity and mortality in SCD. It may be diagnosed in SCD patients who have a new infiltrate on a chest radiograph.[141] Such patients may also have fever, chest pain, tachypnea, wheezing, and/or cough. ACS is often precipitated or accompanied by lung infection or fat embolism. Hypoxemia is common, and 13% of patients in a recent series required mechanical ventilation.[142] ACS is more common in children but more severe in adults; thus mortality in one large series was 1.1% in patients younger than 20 versus 4.3% in adults. Furthermore, patients who have one episode of ACS are at increased risk (up to an 80% likelihood) of having a recurrence.[143,144]

Progressive sickling in the pulmonary microcirculation has long been thought to play a role in the pathogenesis of ACS. More recent studies point to excessive scavenging of nitric oxide (NO) by abundant free Hb,[145] along with release of other vasoactive mediators and enhanced expression of adhesion molecules, as additional factors favoring vascular obstruction, tissue ischemia, and the prolonged local hypoxia that leads to irreversible sickling.[146–149]

Management of ACS should include an aggressive search for a precipitating causal factors and appropriate measures (e.g., antibiotics for infection) to address such factors as they are identified. General supportive measures such as bronchodilators, supplemental oxygen, and adequate hydration are also appropriate. Transfusion therapy is generally given in more severe cases, including all those requiring mechanical ventilation.[141,150] Simple transfusion and RCE have never been systematically compared, but both have deemed helpful in series that lacked any comparison with untransfused controls. RCE seems particularly apt for patients with

relatively high hematocrits who could not receive much HbA via simple transfusion without raising the hematocrit above recommended levels. In the randomized trial of prophylactic transfusion to prevent strokes, ACS was less frequent in the group receiving transfusions (2.2 vs 15.7 events per 100 patient years).[151]

Chronic progressive pulmonary hypertension is another important cause of pulmonary morbidity and mortality in SCD patients that is distinct from ACS.[152] It has been suggested that long-term RCE might, by reducing plasma Hb and increasing NO availability, be beneficial to SCD patients with early pulmonary hypertension recognized by echocardiographic screening.[152,153]

Priapism

Priapism is a prolonged, painful penile erection. Its pathogenesis in males with SCD presumably involves a self-perpetuating cycle of sickling and stasis in engorged penile vessels. In one survey, 27.5% of male SCD patients between the ages of 5 and 20 years reported at least one brief episode (median duration of 60 minutes) of priapism, and the actuarial probability of having at least one episode by age 20 years was estimated to be 89%.[154] More prolonged episodes are less frequent but can lead to penile fibrosis and impotence.[155,156]

Initial treatments for episodes lasting several hours may include hydration and analgesics. If detumescence is not achieved, penile aspiration and/or intrapenile injection of a dilute epinephrine solution may be tried. Surgical shunting may be performed as a last resort in prolonged, resistant episodes, although this can also lead to impotence.[157,158]

Transfusion therapy including RCE has been recommended for resistant episodes and is often tried.[159] Use of RCE has been reported with enthusiasm, although not all patients have responded.[160–164] In a recent series, however, only one of seven patients responded to RCE implemented 1 to 7 days into an episode of priapism when other measures had failed.[165]

Use of RCE for priapism is occasionally followed in a matter of days by neurologic events, including stroke (CVA; *a*ssociation of *p*riapism, *e*xchange transfusion and *n*eurologic events; ASPEN syndrome).[166] This has been attributed to an increase in an already relatively high post-transfusion hematocrit when intrapenile red cells are released during detumescence, and a consequent increase in blood viscosity, perhaps exacerbated by release of vasoactive mediators from the same source.

Use of RCE for refractory priapism must be regarded as problematic at this time. Its value in terminating episodes has not been established in controlled trials, although it is possible that earlier implementation might give better results than the "last ditch" implementation tried in some trials. Conversely, RCE has been linked to a potentially serious adverse event, albeit one that might be avoided by maintaining post-RCE hematocrit at less than 30%. The question of whether prophylactic RCE might prevent recurrent attacks, as it does with strokes and ACS, has also not been examined in a controlled trial.

Severe Pain Crisis and Multiorgan Failure

The uncomplicated pain crises that are the most frequent complication of SCD are usually self-limited and brief. They do not seem to be appreciably shortened by RCE.[161] Prolonged, severe pain crises, conversely, may entail considerable suffering and disability and may occasionally be followed by otherwise unexplained death.[167,168] In addition, a potentially fatal multiorgan failure syndrome has been described after severe painful crises in patients with historically mild SCD and relatively high baseline hematocrit levels.[169] Aggressive transfusion was associated with better outcomes in such patients, with the best outcomes seen in patients having RCE. Preemptive RCE might therefore be considered for a patient with an unusually prolonged severe crisis, especially if the hematocrit is high.

An occasional SCD patient has pain crises so frequently as to become almost continuously disabled. Anecdotal experience indicates that maintenance RCE can reduce or eliminate future crises in such patients and thereby improve quality of life.[118] This conclusion is supported by the reduced frequency of pain crises observed among patients in the transfusion arm in a randomized trial of maintenance transfusion for stroke prevention.[170]

Perioperative Management

SCD patients have long been considered to be at increased risk for morbidity and mortality after general anesthesia and surgery.[171,172] This has been attributed in part to perioperative development of metabolic circumstances that favor sickling, such as dehydration, hypoxia, and acidosis. Prophylactic preoperative transfusion strategies, including RCE to increase HbA to 70%, have been widely recommended and practiced.[173] Improvements in anesthetic technique, however, have decreased the likelihood that circumstances favoring sickling will occur during anesthesia, leading some to question whether routine perioperative transfusion is necessary for all SCD patients.[174]

Four large studies have furnished data that bear on this question. A prospective but nonrandomized multicenter survey of 1079 surgical procedures in SCD patients revealed no advantage for transfused patients homozygous for HbS in the overall postoperative complication rates for low-risk (17.3% vs 18.6%) or moderate-risk (23.9% vs 18.6%) surgeries. Transfused patients with hemoglobin SC disease had a lower complication rate for moderate-risk surgeries (24.5% vs 42.9%). All patients having high-risk surgeries received perioperative transfusions.[175] A randomized study in 604 low- or moderate-risk surgeries compared an aggressive preoperative transfusion strategy (to increase HbA to ≥70%) to a more conservative strategy (to increase Hb to ≥10 g/dL).[176] No difference was found in the postoperative complication rates between the two groups except that complications of transfusion were more frequent in the aggressively transfused patients.

Two other studies followed up patients having similar surgeries who were either randomized preoperatively to the aggressive or conservative transfusion regimens previously described, or "registered" as preoperatively nontransfused or transfused. A study of 364 cholecystectomies (moderate-risk procedures) included 234 randomized patients and 134 registered patients, 37 of whom were nontransfused. The overall complication rate was 39%. Sickle cell–related events such as pain crisis and ACS were more frequent in the nontransfused group, but no other differences in outcome were apparent between the two randomized arms.[177] A study of 138 low- and moderate-risk orthopedic procedures included 74 randomized procedures and 64 "registered" procedures, 24 of which were done without preoperative transfusion. The overall rate of serious complications was 67%. The only significant

difference in complication rate across the four groups was that ACS was more common in both the untransfused (21%) and aggressively transfused (21%) groups.[178]

These studies do not permit a definitive conclusion regarding the necessity of preoperative transfusion in low- and moderate-risk surgeries, but they do suggest that RCE to increase HbA to ≥70% is not warranted. For high-risk (intrathoracic or intracranial) surgeries, however, perioperative transfusion or RCE continues to be the standard of practice.

Pregnancy

Although most pregnancies in women with SCD have a satisfactory outcome, certain complications are more frequent. A recent survey comparing SCD and control pregnancies confirmed increased risks for spontaneous abortion, prematurity, low-birth-weight infants, and postpartum infection. The risks of hypertension and preeclampsia are not increased above controls, and the incidence of pain crisis is not increased above patient-specific baselines.[179–181]

The possibility that prophylactic transfusion, particularly in the third trimester, might improve the outcome of SCD pregnancies has been the subject of a number of uncontrolled surveys. Some of these have concluded that transfusion has a favorable effect.[182–185] One has recommended third-trimester prophylactic transfusion for all SCD pregnancies despite finding that this practice did not improve obstetric outcomes.[186]

A single prospective controlled trial has addressed this question. Seventy-two pregnant women with SCD were randomly assigned before week 28 of gestation to receive either prophylactic transfusion to increase Hb to 10 to 11 g/dL or selective transfusion only if Hb was less than 6 g/dL. The incidence of pain crisis was decreased in the prophylactic transfusion group, but no difference between the two arms was found for any other outcome.[187] Mindful of adverse effects of transfusion, these authors recommended it only for treatment of SCD-related complications, such as ACS, that had actually arisen in association with pregnancy.[188]

The precise role of RCE as a method of delivering transfusion therapy in this context has not been directly examined; however, several reports indicate that it can be carried out safely during pregnancy, even in the outpatient setting.[182,184,185,189,190]

Hepatopathy

A variety of liver problems can develop in patients with SCD, several of which arise as complications of transfusion. Iron overload is almost inevitable with long-term transfusion therapy; however, as mentioned earlier, its onset can be delayed by using RCE instead of simple transfusion. Acute and chronic viral hepatitis are other potential hazards that are theoretically more common with RCE because it requires more donor exposures than simple transfusion. Currently, however, the risk of viral hepatitis is quite low with either approach.[191]

Acute liver disease that is deemed to be a consequence of intrahepatic sickling may also occur. In some cases, it may be further complicated by intrahepatic cholestasis, leading to very high bilirubin levels, or by sequestration of a large volume of red cells in an engorged liver; both of these syndromes are potentially fatal.[191] Scattered case reports have suggested that exchange transfusion (ET) can reverse intrahepatic sickling.[192,193] RCE has been recommended for hepatic as well as splenic sequestration crisis on the theoretic grounds that it can increase HbA without increasing the hematocrit to a level that could become dangerously high if sequestered red cells were to be rapidly released back into the bloodstream.[191,194]

Malaria and Babesiosis

Malaria

Malaria is a mosquito-borne illness caused by several protozoal species of the genus *Plasmodium* that can parasitize red cells. The most severe infections are due to *P. falciparum*, which can infect circulating red cells of any age and therefore causes higher levels of parasitemia than other species that can infect only reticulocytes. Severe malaria with parasitemia greater than 5% can include cerebral, renal, and/or lung dysfunction as well as profound anemia and disseminated intravascular coagulation. Parasitized red cells swell and develop increased adherence to vascular endothelium; they may therefore contribute directly to organ failure via microvascular obstruction and ischemia. An alternative mechanism for tissue damage has been proposed that implicates high levels of cytokines, especially tumor necrosis factor-α (TNF-α) and interferon-γ (IFN-γ); however, these two mechanisms are not necessarily mutually exclusive.[195]

Most patients with malaria can be cured by antimicrobials such as chloroquine. Even *P. falciparum*, which is often chloroquine resistant, is usually sensitive to quinine, quinidine, or artemisinins.[196] In patients with severe or resistant disease and high levels of parasitemia, some form of ET has been used as a means to remove both the infectious agent and potentially obstructive red cells. The literature contains many case reports and small series describing patients who had a prompt decrease in parasitemia and concomitant clinical improvement after ET.[197–203] The only randomized study unfortunately had insufficient power to be meaningful.[204] In contrast, a meta-analysis of eight case-control studies encompassing 279 patients found no survival advantage for patients who received ET. However, the meta-analysis also concluded that exchanged patients were sicker than controls.[205]

Most patients in the aforementioned reports received manual whole-blood ET rather than automated RCE. Some authors contend that removal of TNF-α, IFN-γ, and/or other pro-inflammatory mediators in plasma may contribute to a beneficial effect from ET. If this is the case, it would be important because, although RCE will reduce parasitemia faster with less hemodynamic alteration, it would not be expected to deplete mediators of inflammation. Few data support these contentions, however,[206] and I deem it unlikely that low-molecular-weight cytokines with relatively short half-lives could be meaningfully depleted by the exchange of plasma inherent in ET. Additional treatment with TPE has been reported for this purpose[207] but is again deemed unlikely to produce therapeutically meaningful depletion.

Further studies of ET in malaria are clearly needed but are likely to be problematic. ET and RCE are reported most frequently from developed countries where safe donor blood is readily available and where most patients with malaria are travelers who have no underlying immunity. In contrast, the vast bulk of malaria occurs in underdeveloped areas where safe donor blood is often not available and where many individuals have partial immunity that influences disease outcome. Thus randomized studies in endemic areas would be challenging both to conduct and to interpret.[194] Nevertheless, based on current information, the World Health Organization

recommends that ET be done for malaria, if safe blood is available, in patients with severe disease and parasitemia greater than 10%, and in any patient with more than 30% parasitemia.[208] Severe malaria has been rated a category III indication for RCE by ASFA[6] and AABB[7] (see Table 56–4).

Babesiosis

Babesiosis also is a protozoal red cell infection. It is endemic in wild and domesticated mammals in many parts of the world. *Babesia microti* infection occurs in deer, mice, and other animals in the northeastern and upper midwestern United States and can be transmitted to humans by tick bites.[209] Most cases in immunocompetent individuals are mild, and the incidence of immunity in endemic areas exceeds that of clinical disease, suggesting that subclinical cases are common. Severe disease with high fever, profound anemia, cardiorespiratory and/or renal failure, and coma may occur, however, and is more likely in immunodeficient or asplenic patients.[209]

Babesiosis usually responds to antimicrobials; however, reduction in parasitemia accompanied by clinical improvement has been reported after ET or RCE in several patients with severe, resistant disease.[210–213] Here also the question of mediator depletion as an extra therapeutic benefit of whole-blood ET has been raised in the absence of supporting data.[209] Controlled trials are lacking, but some authorities recommend ET or RCE for severe cases of babesiosis with more than 5% parasitemia.[209] Severe babesiosis is rated as a category III indication for RCE by ASFA[6] and AABB[7] (see Table 56–4).

D. Cellular Therapies and Tissue Banking

Chapter 57

The Role of Transfusion Medicine in Cellular Therapies

Simon Mantha • Edward L. Snyder

Over the past 2 decades, blood bank and transfusion medicine specialists and practitioners have been called on to expand their traditional roles of collection, processing, storing, and administering blood components derived from human whole blood or via apheresis, to the manipulation, processing, storage, and administration of other human cell and plasma-based therapeutic elements, and to assisting the scientists and clinicians involved with these concepts or procedures. Thus the field of "blood banking" has evolved into "transfusion medicine and cellular therapies." Perhaps an even broader application of transfusion medicine and requiring expertise in collection, manufacture, processing, storage, and administration, along with its increasing regulation, is the addition of the hospital tissue-banking function described in the final chapter of this text. Thus, what has only recently come to be called "transfusion medicine and cellular therapies" is now undergoing additional definition and falling under the abbreviation "HCT/P" for "Human Cellular and Tissue-Based Products." Indeed, those framing the mission statement for the American Association of Blood Banks (AABB) adopted the terminology of "transfusion medicine and cellular and related biological therapies" to cover the continually evolving arena in which the transfusion medicine practitioner is found. It is the cellular and related biologic therapies and the HCT/Ps that are the subject of this section of this textbook. This chapter provides an overview of the role of transfusion medicine in cellular therapies, with subsequent chapters providing more detail on peripheral blood, bone marrow, umbilical cord blood progenitor cells, mononuclear cell and related preparations, and tissue banking in the hospital setting.

ORIGINS OF "BLOOD BANKING"

Blood banks, initially and traditionally, have been involved in the collection, storage, and use of blood products containing mature, end-stage cellular blood elements with no potential for further mitosis or expansion, including red blood cells, platelets, and granulocytes. Red blood cells were the first cellular constituent of human blood for which standardized, reliable methods of collection, storage, and administration were established. Instrumental to the ability to transfuse red blood cells safely was the discovery of the ABO system by Landsteiner in 1901.[1] Then, the use of sodium citrate as an anticoagulant, pioneered by Albert Hustin in 1914, and the development of refrigerated storage by Richard Weil allowed the creation of a "blood depot" by Oswald Hope Robertson in Great Britain during World War I.[2] By 1940, the first Blood Bank had been established in the United States by Bernard Fantus in Chicago.[3] Eventually procedures were developed to separate whole blood into its different components, so that red blood cells, platelets, plasma, and its various fractions could be stored and administered individually.

BONE MARROW TRANSPLANTATION

The First Years of Bone Marrow Transplantation

Bone marrow transplantation (BMT) inaugurated the era of modern cellular therapy, in which the cells transferred to the recipient engraft and divide in vivo, thus generating long-term therapeutic effects.[4] Initially, the role of transfusion medicine in BMT was basically to support the transplant procedure by providing the patient with appropriate red blood cells and platelets via transfusion. Minimal if any manipulation of the stem cell products was done by the Blood Bank, as was seen in E.E. Osgood's report of an attempt to treat aplastic anemia with injections of crude marrow extracts.[5]

By 1960, Dr. E. Donnall Thomas[6] initiated trials on dogs before attempting bone marrow transplantation in humans, by using intravenous infusion of allogeneic donor bone marrow aspirated from the iliac crest and filtered to remove aggregates and fat. In many instances, the preparative regimen was minimal, especially in patients treated for aplastic anemia. Initial procedures almost always resulted in death, either from lack of engraftment or "secondary disease," the entity that would be later referred to as graft-versus-host disease (GVHD).[7] The only successful procedures were those in which the donor and the recipient were identical twins. In those syngeneic transplants, the two individuals shared the same cellular antigens, and histoincompatibility was not an issue. Consequently, clinical interest in bone marrow transplantation decreased after 1962, when it became clear that

a better understanding of the immune processes involved would be necessary before its more widespread application.

Such advances would come in the early 1970s, with elucidation of the physiologic role of the human leukocyte antigen (HLA) system.[8–11] Initial demonstration of inherited determinants that affected the tolerance of transplanted allogeneic tumors in mice dates back to 1916.[12] Twenty years later, Gorer[13,14] identified the murine major histocompatibility complex (MHC). The human equivalent to the mouse MHC was discovered independently in the form of the HLA system, when it was found that the sera of some multiparous women and blood donors contained agglutinating antibodies against allogeneic leukocytes.[15–17] This led to the identification of type I HLA antigens. Discovery of the type II HLA allelic group occurred with the advent of the mixed lymphocyte culture (MLC) technique. Advances in molecular biology in the 1980s allowed localization of the genomic sequences involved and provided a detailed knowledge of the amino acid sequences they encode.[18] This would prove instrumental in improving the quality of matches for patients undergoing allogeneic stem cell transplant, thus helping to decrease the morbidity and mortality associated with GVHD.[19]

The immune attack mounted by the immunocompetent donor lymphocytes against the recipient's cells was eventually found to be a significant contributor to the long-term remissions observed in some hematologic malignancies, and this phenomenon was named the graft versus leukemia/lymphoma effect (GVL). However, to date, induction of GVL often occurs in parallel with the untoward effects of GVHD. Whereas immunosuppressive agents have been administered to patients to control acute GVHD,[20] chronic GVHD is less responsive, and still no effective treatment exists for this devastating complication.[21]

Refining the Transplantation Process

The stage for the involvement of transfusion medicine in the collection of hematopoietic stem cells (HSCs) was set by the coming together of three events: the development of apheresis technology, the identification of the CD34 antigen as a marker of early progenitors, and the identification and synthesis of granulocyte colony–stimulating factor (G-CSF) and granulocyte-macrophage CSF (GM-CSF).

Leukapheresis

Leukapheresis had initially been designed as a palliative treatment for leukemia by decreasing the disease burden, with only limited efficacy.[22] In the beginning, patients with chronic myelogenous leukemia were treated with leukapheresis. Later, this technique was used as a treatment modality for hyperleukocytic acute myeloid leukemia, with published reports confirming the beneficial effects of cytoreduction on cerebral leukostasis.[23] In the latter condition, the efficiency of cell removal is higher because of cell-density considerations. Finally, leukapheresis has been used to collect granulocytes to transfuse into neutropenic patients with bacterial or fungal infections. Such colonization by opportunistic infections is a common and often lethal complication of myeloablative chemotherapy. Unfortunately, to this date, no documentation of a survival benefit is attributable to granulocyte transfusion, probably because of the low cell doses used in most published studies. This might change with new clinical trials using G-CSF–mobilized neutrophils.[24]

Because it had been shown that humans have small amounts of circulating hematopoietic progenitors at any one time, the idea of processing large volumes of peripheral blood for isolation of the mononuclear cell fraction emerged as an alternative to bone marrow aspiration in the operating room.[25] Early efforts at peripheral blood stem cell harvest from an unstimulated allogeneic donor yielded products that failed to engraft, probably because of an insufficient number of cells collected.[26] Later attempts by Dr. Ann Kessinger[27,28] at the University of Nebraska, using multiple apheresis sessions in steady-state donors, were more successful. It had been observed, however, that 2 weeks after chemotherapy, the number of hematopoietic progenitors in the peripheral blood more than doubled.[29] The exact mechanism by which this occurred was not well understood, and the term *mobilization* was used to describe the exit of cells from the marrow and into the blood stream. This had the potential to allow completion of the collection process in a shorter time.

An unexpected benefit, however, was that for the same amount of early progenitor cells infused, peripheral blood–derived products elicited a faster engraftment of neutrophils and platelets.[30] A possible explanation for that effect is that a significant increase in more committed progenitors is observed in the peripheral blood of patients immediately after chemotherapy.[31] Those cells, once transplanted, are thought to take less time to generate mature neutrophils than do the pluripotent stem cells in the bone marrow, which are less differentiated and take longer to mature. Shortening the duration of the nadir for both granulocytes and platelets is a major concern in HSC transplant, as most early complications occur in the vulnerable period when the absolute neutrophil count is less than 500 cells/μL and the platelet count is less than 20,000 cells/μL. Of note, apheresis products contain more lymphocytes than do those derived from marrow. However, they do not seem to cause significantly more GVHD, and their use in hematologic malignancies might be associated with a better disease-free survival.[32]

The transfusion medicine service performs apheresis in most United States medical centers where this therapeutic modality is available. It follows stringent regulations that determine how the procedures are done and who can perform them (i.e., level of training and supervision). The blood bank is therefore well suited to be in charge of the peripheral blood stem all harvest process, as it is basically a variant of leukapheresis. Additionally, because processing and storage of the product is usually also performed in the blood bank, the whole sequence from harvest to delivery can be kept under the supervision of one entity, which greatly facilitates quality control.

Refinements in the apheresis techniques also opened the door to donor lymphocyte infusions (DLIs), a new application designed to harness the therapeutic effects of GVL without going through conditioning of the patient and aspiration of marrow from the donor. Individuals who had donated stem cells were asked to provide lymphocytes to the recipient whose disease had relapsed. This proved to be of particular benefit in chronic myeloid leukemia, in which responses were observed in most patients.[33] Infused donor lymphocytes were also shown to be useful in fighting infection by cytomegalovirus (CMV) and Epstein-Barr virus (EBV). Such a transfer of active immunity to the immunosuppressed recipient can help control a potentially lethal condition. Even though the doses of cells used to treat a viral infection are lower than those for relapsed leukemia, the potential to induce GVHD is

present in both settings. The blood bank is accordingly very involved in the collection and storage of lymphocytes, as this procedure requires leukapheresis and, often, cryopreservation of a white blood cell fraction.

CD34+ Cell Identification

The science of transplantation passed another milestone when Dr. Curt Civin[34,35] at Johns Hopkins Medical School created a monoclonal antibody against an antigen present on hematopoietic progenitor cells capable of long-term engraftment. Mice were immunized against poorly differentiated human myeloid cells from the KG-1a line, by intraperitoneal and intravenous injection. The mouse spleen cells were fused with murine plasmacytoma cells. Hybridomas were then screened for production of an antibody that would bind KG-1a cells but not human granulocytes. The corresponding antigen was initially called My-10, but its designation would eventually be changed to CD34. This seminal discovery would allow a better assessment of the graft and its potential to reconstitute hematopoiesis in a particular donor, thereby improving standardization of the transplantation process. Additionally, use of such an antibody would permit positive selection of HSCs before transplant as a way to deplete the graft of undesired cellular elements.[36–39]

This technique is still used today to decrease the number of lymphocytes in the graft, to reduce the incidence of GVHD.[40] The procedure is usually performed with a commercial immunomagnetic selection apparatus, operated under strict aseptic conditions or within a closed system.[41] Paramagnetic beads are covered with a monoclonal antibody directed against the CD34 antigen. When put in contact with the stem cell product, the early progenitors expressing CD34 are bound to the beads. Exposure of the cell suspension to a strong magnetic field results in separation of the CD34-positive cell fraction from the remaining of the product. Some systems use a releasing agent to free the isolated cells from the paramagnetic beads before storage or infusion into the patient.

To ensure quality at all steps of this complex process and ultimately the safety of the patient, it should be undertaken only by thoroughly trained staff working under expert supervision. The product must be sampled for assessment of leukocyte populations by flow cytometry, and critical calculations must be done to ensure that the adequate amounts of reagents are mixed with the cells. The selection process itself is now essentially automated, but often the device will require intervention by the operator. The blood bank is the ideal setting to accomplish this, given its long history of processing cellular products and ensuring quality control. Blood bank quality systems also provide for strict adherence to current good manufacturing practices (cGMP) during the entire CD34+ selection process.

Hematopoietic Growth Factors

The growth of HSC transplantation accelerated with the development and commercialization of G-CSF and GM-CSF. Both of these cytokines improved the efficiency of peripheral blood stem cell collection via apheresis. The existence of these cytokines and their effects on committed progenitors were well known in the early 1980s,[42] but industrial production by means of recombinant DNA technology became feasible only after the genes were cloned.[43,44] It was soon demonstrated that when used as single agents, G-CSF and GM-CSF mobilized HSCs into the peripheral blood.[45,46] This effect is further improved by combination of any one cytokine with chemotherapy, but not much when only the two cytokines are combined together.[47] The physiology of cytokine-induced mobilization is being studied intensely, and researchers understand the mechanism(s) of mobilization much more clearly than they had previously. It is thought that on exposure to pharmacologic doses of the agent, progenitors already present in the marrow release their attachments to osteoblastic stromal cells and enter the peripheral circulation. For example, it is thought that G-CSF acts by promoting release of proteolytic enzymes from granulocytes, which cleave the bond between progenitor cells and the marrow stromal cells.

An interesting investigational drug that works through a different mechanism is AMD-3100. It selectively blocks the binding of CXCR4 receptor present on leukocytes with CXCL12 present on osteoblasts. This bond mediates adhesion of hematopoietic progenitors to marrow stromal cells. Blockade of the receptor results in a shift of those progenitors to the peripheral blood. Use of this drug is now being evaluated in clinical trials for patients who do not mobilize enough stem cells with current modalities.[48] Cytokines other than G-CSF and GM-CSF have been used to achieve mobilization, including stem cell factor (SCF), erythropoietin (EPO), interleukin 3 (IL-3), interleukin 6 (IL-6), and FLT3 ligand.[49–53] Single-agent G-CSF or GM-CSF, however, remains the standard regimen for healthy donors, with tolerable acute toxicity and no evidence of long-term effects on hematopoiesis.[54] Patients often experience bone pain and headache. Thrombocytopenia is often noticed but usually is not severe. Splenomegaly is common, but splenic rupture is a very rare event.

As the use of HSC transplantation became widespread, blood banks and their staff became more involved clinically. They were instrumental in streamlining the collection process, which is often logistically complex, as it involves careful timing between start of mobilization (cytokine with or without chemotherapy), assessment of peripheral blood CD34+ cell counts, central-line placement, and start of apheresis. The kinetics of mobilization vary from one patient to another, and the experience of the transfusionist in that matter is crucial in ensuring that the collection goal is met.

Emergence of a Body of Regulations

As HSC transplantation continued to grow, it became clear that programs for practices, standards, and accreditation needed to be firmly in place. The AABB (formerly the American Association of Blood Banks) developed a series of standards for cellular therapy (starting in 1991, addressing hematopoietic cellular therapy and more recently relating to cellular therapy, in general), as well as an accreditation program designed to support the adherence to these standards. The Food and Drug Administration (FDA) originally determined that bone marrow would be considered within the practice of medicine and therefore would not be regulated. However, when peripheral blood stem cell collections were being developed, the FDA mandated that these biologics would need to be regulated, as was the blood industry. Other organizations, such as the Foundation for Accreditation of Cellular Therapies (FACT), also developed standards for the laboratory and clinical aspects of stem cell transplantation. Strict adherence to these standards is critical to ensure that the process of HSC transplantation is performed under

conditions of maximal safety and quality. The opportunity for the blood bank or hospital transfusion service to play a role in this process is clear.

The National Marrow Donor Program

The requirement for a compatible family member has often limited the use of allogeneic stem cell transplantation, creating the need for a large, nationwide stem cell donor bank. Early proponents of such an organization were Robert and Sherry Graves from Colorado. Their 10-year-old girl Laura had developed acute leukemia and needed a bone marrow transplant. After a search involving platelet donors, an HLA-matched individual was found. Realizing that other families shared the same struggle, Robert Graves became an advocate for the creation of a national marrow donor registry. In 1984, Congress passed the National Organ Transplant Act, which among other things evaluated the feasibility of a national marrow donor registry. Thanks to the support of Congressman Bill Young (R-FL), the National Bone Marrow Donor Registry (NBMDR) began operating in 1986. Its goal was to provide matched unrelated transplants for anyone in need of a stem cell or bone marrow transplant. By the end of that year, 39 donor centers were already affiliated with the organization. The Registry was originally supported by the AABB, the Council of Community Blood Centers (now America's Blood Center), and the American Red Cross (which administered the program), in addition to funds from Health Resources and Services Administrations (HRSA) and the Navy. In 1988, its name was changed to National Marrow Donor Program (NMDP).

In 1990 the organization took charge of its administration and became a nonprofit entity separate from the Red Cross. The Transplant Amendments Act of 1990 further codified its functions. As this program continued to grow, peripheral blood stem cells as the source for transplants caught up with and exceeded the percentage of BMTs. In current practice, the majority of grafts are collected from peripheral blood, mainly because of their faster engraftment and ease of collection.

UMBILICAL CORD BLOOD

Another major source of HSCs was evaluated and established by Dr. Harold Broxmeyer[55] when he identified umbilical cord blood as being rich in these cells. Benefits already obvious at that time were availability of the resource, ease of collection, and absence of risk to the donor. One major inconvenience, however, was the limited amount of hematopoietic progenitors available in one sample, making it difficult to use in adult recipients. The first case of a patient receiving an umbilical cord blood progenitor cell transplant from a sibling donor was reported in 1989.[56] Applicability of this treatment in the unrelated allogeneic setting was evaluated, and it became obvious that a cord blood bank would be necessary to ensure availability of adequately matched products for potential recipients.[57] Dr. Pablo Rubinstein[58] established the first umbilical cord blood bank at the New York Blood Center in 1992. The NHLBI fostered the development of this program with the establishment of the Cord Blood Transplantation Program (COBLT). This effort resulted in the large-scale collection and storage of umbilical and placental stem cells in both public and private umbilical cord blood banks.[59] Now umbilical cord blood is considered a good alternative to marrow for pediatric HSC transplant, especially given the lower risk of acute and chronic GVHD with cord blood.[60]

Again, because the technology was similar to that of peripheral blood stem cell collection and manipulation, the FDA chose to regulate the cord blood field as a manufacturing process rather than within the practice of medicine. This was done to ensure the quality of the product, its appropriate storage, and that the highest levels of cGMP and current good tissue practices (cGTP) were being followed. As illustrated by the experience of the New York Blood Center, the blood bank was involved from the beginning in cord blood storage. Its familiarity with cryopreservation of cells but also its ability to keep a large registry of products were instrumental in the success of this enterprise. Today, cord blood banking is being monitored and regulated by Congress (HR 2520) with the responsibility for administrative oversight being assigned to HRSA (Health Resources Service Administration). This Bill will help to ensure that cord blood is available to patients of all ethnic backgrounds and that the stem cells will be of the highest quality. Blood banks and hospital transfusion services will clearly have an opportunity to play a major role in this process.

OTHER STEM CELLS

The field of stem cells expanded yet again when researchers showed that bone marrow–derived cells (BMCs) are able to become epithelial cells specific to various organs and tissues such as the liver, pancreas, kidney, central nervous system, gastrointestinal tract, skin, cardiac muscle, and skeletal muscle.[61–70] A debate is going on as to whether this really is transdifferentiation (supporting the hypothesis of stem cell plasticity) or, alternatively, a fusion process.[71–74] It is possible that both processes are occurring. The exact nature of BMCs involved is still largely unknown, and if fusion is the underlying mechanism, then they are likely hematopoietic cells. At this point, only two distinct marrow populations capable of self-renewal and multilineage differentiation have been well characterized: HSCs and mesenchymal stem cells (MSCs). MSCs can give rise to adipocytes, chondrocytes, and osteoblasts.[75,76] Attempts at clinical applications in humans have yielded encouraging results, notably in the treatment of osteogenesis imperfecta, a congenital disease characterized by defective synthesis of type I collagen, which causes brittle bones.[77] Other potential uses include repair of bone and cartilage at sites of trauma.[78] The blood bank will likely be involved in the storage and manipulation of MSCs, given its existing record with HSCs. Blood banks could also be involved in the harvesting process, depending on the anatomic site of origin.

REPAIRING THE HUMAN BODY (REGENERATIVE MEDICINE)

Regenerative medicine is the new name for the field previously referred to as tissue engineering. The potential for using stem cells of various types to replace human tissues and even organs appears limitless at this time.

Pancreatic Islet Cells

Pancreatic islet cell transplantation is one emerging application that is used for the treatment of type I diabetes. Efficient

processing of the pancreas to obtain a highly purified preparation was first described by Dr. Camillo Ricordi in 1988.[79] However, attempts at transplantation in the 1990s usually gave short-lived results, as the allogeneic cells were quickly destroyed by the host's immune system. Graft survival improved with the introduction of a new, glucocorticoid-free immunosuppressive regimen in 2000.[80] Research is ongoing to better prevent rejection, if possible without the use of immunosuppression, which is a significant cause of complications for this procedure.[81,82] Although blood banks are not as involved in retrieval of the cells, they could participate in the processing.

Cell Therapies in Myocardial Infarction

Acute treatment of myocardial infarction aims at early reperfusion, but patients who survive the initial event often develop cardiac failure due to ventricular remodeling. This process is characterized by replacement of the dead myocardium by fibrous tissue, which eventually undergoes expansion, with secondary dilation of the ventricular cavity.[83] Animal studies suggested that stem cells could differentiate into myocardial cells and regenerate infarcted tissue.[84] Early trials in humans revealed the safety and feasibility of this approach.[85] Some randomized studies have been completed, with variable initial results.[86–88] More time is needed to appreciate fully the impact of such a treatment on the natural history of those patients.

IN VITRO AND IN VIVO REGENERATION

Although scientists have become better at handling and administering single-cell suspensions, as illustrated in the previous examples, much more must be learned for the field of regenerative medicine to proceed to the next step: the in vitro or even in vivo generation of functional tissue elements of adequate size, possessing the necessary physical, electrical, and metabolic properties to support normal function.[89–93] Such engineered tissues would be able to replace abnormal or diseased human structures (for example, skin, bone, muscle, tendons, blood vessels, or corneas). Ideally, autologous cells would be used to avoid the transmission of viruses and prions. In this process, the starter cells are expanded in vitro and used to seed a support structure (mandril). These structures can be made of either permanent materials such as ceramic or bone or biodegradable materials such as seaweed or alginates. Once the cells have grown in vitro, the mold is ready to be implanted in a human host to replace a damaged body tissue or eventually even an organ. After the cells and the mold are implanted, over a period of time, the implanted cells grow and differentiate so that they are able to replace the damaged tissue and restore normal function. Ceramic molds, for example, are used to repair bony abnormalities, whereas degradable molds are used for blood vessel repair.

Expansion of these cells and creation of an artificial tissue or even organ would probably occur in a designated facility, as the process will certainly require very specialized staff and equipment. The experience of the blood bank with maintenance of an inventory of cellular products and all the related quality-control issues will make transfusion services the best candidate for the collection, storage, processing, and distribution of these biologics in the hospital setting.

GOVERNMENTAL OVERSIGHT

The FDA has exercised oversight of blood and blood components for almost 4 decades. In the 1990s, they started developing regulations for other human cells, tissues, and cellular and tissue-based products, including peripheral blood stem cells. The FDA derives its regulatory power from the Public Health Service Act, Sections 351 and 361. Title 21 CFR Part 1270, under Section 351, governs the collection, storage, and manipulation of human cells and tissues from unrelated donors. Title 21 CFR Part 1271, under Section 361, covers minimally manipulated autologous and allogeneic cellular products of first- and second-degree relatives and includes the most recent regulations on cellular therapies. The first Final Rule of 21 CFR Part 1271, published on January 19, 2001, and effective January 19, 2002, addresses establishment registration and listing of human cells, tissues, and cellular and tissue-based products (Subparts A and B). Published on May 25, 2004, the second Final Rule of 1271 covers eligibility determinations for donors (Subpart C). The third Final Rule (Subpart D) establishes standards for current Good Tissue Practices (cGTPs) and was published on November 24, 2004, to become effective at the same time as the Donor Eligibility Final Rule (Subpart C), May 25, 2005. The FDA inspects registered facilities on a regular basis to ensure compliance. Importantly, many aspects of the new field of regenerative medicine does not clearly fall under the current regulatory guidelines. Some techniques, for example, may involve collection of bone marrow from the autologous donor for use in the operating room. Regulations will likely be developed to address these areas. Here, too, specialists in transfusion medicine will likely play an advisory and consultative role to the FDA.

THE NEW BLOOD BANK

The term *transfusion medicine* was coined in the 1980s by the late Dr. Tibor Greenwalt and by Dr. Fann Harding, then of the NHLBI. The efforts of those and other visionaries led to the NHLBI-sponsored Transfusion Medicine Academic Awards (TMAAs), which were awarded to about 40 medical schools during the 1980s and 1990s. This federal program provided enormous impetus for researchers to study the science of transfusion, and this resulted in the attraction of many of the current transfusion leaders into the field. Although blood banking started with collecting, processing, and storing end-stage blood cells, the TMAA program and other factors led, in part, to the field's current involvement with hematopoietic and other types of stem cells. Indeed, at this point, the field of transfusion medicine is deeply involved in the collection, processing, storage, and distribution of HSCs whether the HSCs are from bone marrow, peripheral blood, or cord blood. These core competencies will be built on in the future to ensure the role of the blood bank in the field of regenerative medicine. As other aspects of blood banking will become more automated, the amount of time devoted to traditional blood products and practices by blood banks will likely decrease, with the activities of the transfusion service of tomorrow becoming more oriented toward cell processing in any number of its many facets (Fig. 57–1). The transfusionist will manage an increasingly more complex inventory of products, many of them likely to be standardized cellular suspensions or tissues produced in specialized bio-factories. This will be an exciting era with myriad challenges. However, the central and overriding consideration

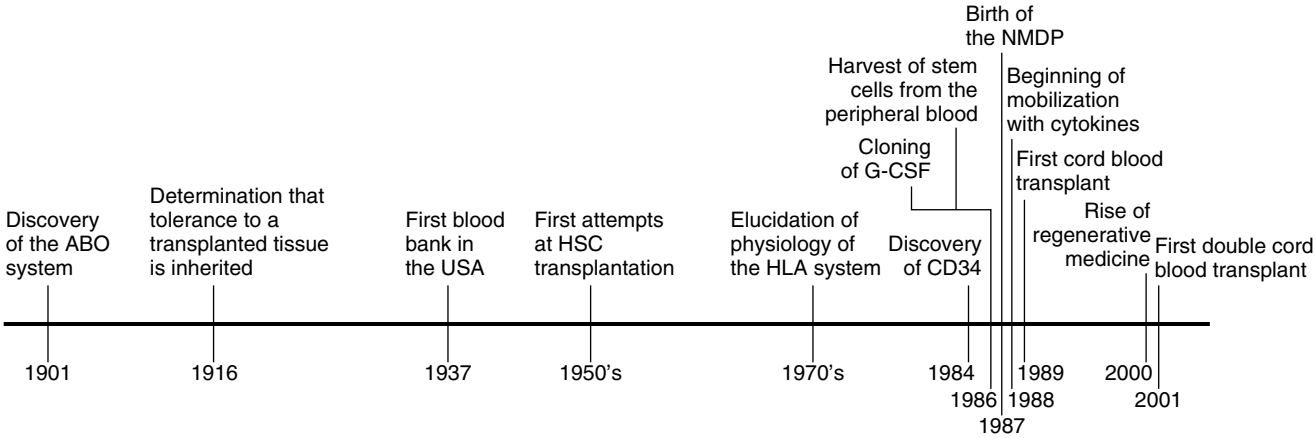

Figure 57–1 Chronology of some major advances in cell therapies.

will always be quality and quality controls designed to ensure that the patient will receive the safest and most efficacious blood-borne material possible, just as it was when transfusion medicine first began in the 19th century.

Chapter 58

Bone Marrow and Peripheral Blood Stem Cell Transplantation

Howard Benn • Scott D. Rowley

INTRODUCTION

The intent of hematopoietic stem cell (HSC) transplantation, regardless of the type of HSC component infused, any modifications of the component performed, and the disease being treated, is to achieve long-term engraftment of the cells infused. HSC transplantation was initially developed to correct the consequences of bone marrow (BM) failure, whether this failure was the result of a disease such as severe aplastic anemia or iatrogenic, resulting from the treatment of disease with administration of dose-intense chemoradiotherapy regimens. Restoration of hematopoietic function after administration of an intensive conditioning regimen in the treatment of those malignant diseases that show a dose-response effect, such as leukemia, continues to be the most common use of HSC transplantation. However, the ability to establish a different immune system in a properly prepared recipient with the resulting graft-versus-disease effect extends the utility of HSC transplantation to treatment of diseases that are not sensitive to escalation of chemotherapy dosage. Furthermore, the ability to establish a lymphohematopoietic chimera with allogeneic HSC transplantation opens the possibility of using HSC transplantation as a foundation for other treatments such as cell-based immunotherapy or solid organ transplantation.

Several thousands of patients undergo HSC transplantation each year, a testament to the facility with which this particular stem cell therapy can be used. Advancements in supportive care including newer antibiotics and the development of pretransplant conditioning regimens with lower nonhematologic toxicities widen the diagnoses and age range of patients who can be treated successfully. The availability of alternate stem cell sources such as umbilical cord blood (Chapter 59) and unrelated volunteer donors extends allogeneic transplantation to patients lacking an appropriate related donor.

TRANSPLANTATION TECHNIQUES

Selection of Patients

Careful patient selection and timing of treatment are critical to the success of HSC transplantation (Table 58–1). For example, in the treatment of cancer, patients with bulky tumor masses or chemotherapy-resistant diseases are much less likely to achieve durable responses, even with the use of dose-intense regimens. The immune suppression required with allogeneic transplantation also may exacerbate underlying infections such as mold infections, viral hepatitis, or tuberculosis. The early introduction of dose-intense therapy in the treatment of a patient, before chemotherapy resistance and excessive chemotherapy-induced organ toxicity develop, is paramount. Therefore, treatment algorithms incorporating HSC-transplant salvage strategies must be part of the initial therapeutic decisions for each patient with a disease possibly treatable by high-dose therapy. Patients being prepared for HSC transplantation will frequently undergo several cycles of chemotherapy, intended to demonstrate the sensitivity of the disease to chemotherapy, reduce the bulk of the disease before transplantation, and facilitate the collection of peripheral blood stem cells (PBSCs).[1] Radiotherapy can be used to debulk large tumor masses but is, in general, reserved for administration after recovery from transplantation because of the deleterious effects of this treatment modality on the collection of PBSCs and the increase in organ toxicity within the treatment field with subsequent administration of chemotherapy.[2] Radiotherapy used as consolidation therapy after autologous transplantation may require the infusion of additional HSCs to offset the marrow-suppressive effects of this therapy, again illustrating the need for comprehensive planning of the patient undergoing HSC transplantation, including possible collection of reserve quantities of HSCs.

Many patients eligible for HSC transplantation using marrow-ablative or reduced-intensity regimens also have comorbidities that can affect the tolerance of the patient to this treatment, possibly increasing the risk of nonhematologic complications. Patients undergo a detailed evaluation to uncover any organ dysfunction that may preclude the safe administration of this therapy. Although HSC infusion rescues the patient from the hematologic toxicity of the conditioning regimen, the nonhematologic (organ) toxicity of dose-intense therapies may be formidable, particularly if a dose-intense conditioning regimen is administered. The presence of single-organ comorbidity or abnormal laboratory values predicts regimen-related nonhematologic toxicities.[3,4] A retrospective review of 383 consecutive transplants noted individual factors predictive of early transplant-related mortality to include a forced expiratory volume $(FEV)_1$ less than 78% of predicted, serum creatinine greater than 1.1 mg/dL, and serum bilirubin greater than 1.1 mg/dL.[4] Unfortunately, many patients, especially older patients, initially have more than a single comorbidity. Investigators in Seattle applied the multiparameter Charlson Comobidity Index to patients undergoing unrelated or related donor HSC transplantation and reported a direct correlation between patient score and

Table 58–1 **Factors Influencing Transplant Decision**

Disease-Related Issues	Patient-Related Issues	Availability of Donor
Diagnosis	Age	Autologous
IPSS score	Performance status	Family member
Previous treatment	Other medical conditions	Unrelated donor
Response to treatment		Umbilical cord blood
Current extent (bulk) of disease		
Current chemotherapy sensitivity of disease		

nonrelapse mortality.[5] (These investigators subsequently published a modified HSC transplant–specific comorbidity index developed from data from 1055 patients that showed better predictive value for nonrelapse mortality and post-transplant survival).[6] For these reasons, the timing of transplantation is critical, and efforts should be made both to reduce tumor bulk and to correct comorbid conditions before initiation of transplant conditioning.

Selection of Donors

A variety of sources of HSCs for transplantation are available, and details regarding the collection, processing, and infusion of marrow, peripheral blood, and umbilical cord blood products are described in Chapters 57–60. All patients storing cells for autologous HSC transplantation and donors for allogeneic (or syngeneic) transplantation must be evaluated for risks involved with the collection of HSCs and the risks to the recipient from diseases of the donor that may be transmitted into an immunoincompetent recipient. Patients undergoing autologous transplantation are not at risk for transmission of infectious diseases but must be evaluated for the risks of the collection procedure (and subsequent treatment). As a broad consideration, donors can be evaluated by using the same criteria currently applied to blood donors, although the United States Food and Drug Administration (FDA) has enacted specific regulations for the handling of certain tissues including PBSCs obtained from allogeneic donors. However, numerous infectious diseases that would not exclude the donor from blood donation, such as cytomegalovirus, may be transmitted with the allograft.[7] Donors who would otherwise be excluded for health reasons from donating blood for transfusion (e.g., history of hepatitis) may still be eligible to donate BM if the needs of the recipient outweigh the risks of disease transmission. Hematopoietic disorders of the donor, such as hemoglobinopathies, will be transmitted to the recipient. Cancer can be transmitted to a conditioned host, as illustrated by the transmission of donor leukemia not detected during initial evaluation of the donor.[8] Standards are now published that describe the evaluation of the donor both for the risk of the donation process and for the risk of transmission of disease to the recipient.[9,10]

Anesthesia and blood loss present the greatest risks of serious complications for marrow collection. Marrow harvesting has the luxury of the intensive support capability of the operating room, allowing collection of patients and donors with significant comorbid conditions. Most marrow harvesting is performed under general anesthesia, which requires intubation for control of the airway for a surgical procedure performed on a prone patient. Regional (spinal or epidural) anesthesia is acceptable for the donor who is not at risk for the hypotension that frequently occurs with this form of anesthesia. Regional anesthesia occasionally fails, so patients and donors who express a preference for this anesthesia must also be counseled about the potential need for general anesthesia. The health assessment of the marrow donor must include questioning about a history of joint disease of the cervical spine and mandible and examination of the mouth if general anesthesia requiring intubation is chosen. Patients and donors with comorbid conditions, such as aortic stenosis or sensitivity to changes in blood volume and blood pressure, may require anesthesia consultation and plans for invasive monitoring during the surgical procedure. A history of marrow fibrosis, previous pelvic irradiation, or pelvic tumor involvement will exclude a patient from marrow harvesting.

In contrast, collection of PBSCs is generally an outpatient procedure conducted in the clinic setting. For this reason, PBSC collection should never be viewed as a safer alternative to marrow harvesting for the donor with underlying health problems. PBSC donation presents its own unique risks resulting from the logistics of cytokine administration and the extracorporeal circulation of blood. The risks of cytokine administration are presented in Chapter 60. Adverse events that have been associated, at least temporally, with the collection procedure include myocardial infarction, cerebral vascular accident, and rupture of the spleen.[11–14] Most donations can be obtained by using a vein-to-vein procedure. Some donors, especially pediatric donors, may require the placement of a temporary central venous catheter. The risks of catheter placement are well known and are not repeated here.

Allogeneic Donors

HLA MATCHING

Human leukocyte antigen (HLA) compatibility is the primary consideration in selection of a donor for allogeneic transplantation. Both major and minor histocompatibility-locus antigens may contribute to host-versus-graft (HVG; with HSC rejection) and graft-versus-host reactions (GVH; resulting in graft-versus-host disease [GVHD]), as shown by the increased risks of engraftment failure and GVHD after HLA-matched allogeneic compared with syngeneic transplantation. HLA antigens are classified as class I (HLA-A, -B, -C) and class II (HLA-DR, -DQ, -DP); typing of donors and patients can be performed by using low- or high-resolution techniques. The low-resolution techniques will discriminate, generally, between antigens (e.g., A02 vs A03, phenotypic matching), whereas high-resolution molecular techniques will identify allelic differences (e.g., A0201 vs A0202, genotypic matching). Various reports describe deleterious effects of mismatching at each of these loci on transplant outcomes, although the effect may not be clinically evident in all patient populations, demonstrating an influence of nongenetic factors on the tolerability of HLA mismatching.[15–19]

Transplantation of HSCs from HLA-disparate donors increases the risk of GVHD and transplant-related mortality, with greater numbers of mismatches increasing these risks of transplantation. Ideally, genotypically matched unrelated donors (URDs) will be available for patients lacking an HLA-identical sibling donor. However, not all ethnic groups are well represented in the various donor registries, and genotyp-

ically matched donors are not available for all patients who are candidates for allogeneic transplantation. What is not known is whether certain allelic mismatches are more permissive than others, allowing the use of mismatched donors without increased risk of adverse outcomes. A large series involving 1874 donor-recipient pairs for whom retrospective high-resolution typing was performed found increased risks of mortality for recipients of HSCs from donors mismatched at a single HLA-A, -B, -C, and -DRB1 locus, with much higher risks for patients with multiple mismatches.[20] The risk of mortality was increased for patients mismatched at either the antigen (low-resolution) or allelic level, although the relative risk was greater for the former. Importantly, 56% of patients matched at HLA-A, -B, and -DR by using low-resolution techniques were found to have one or more mismatches when high-resolution typing for these antigens and HLA-C was performed. These investigators found no additional contribution of mismatching at either HLA-DQ or HLA-DP loci, suggesting that mismatches at these loci can be ignored in the algorithm used for the selection of a URD. Similar findings regarding the importance of HLA-DR, but not HLA-DQ or -DP matching was reported in another large (831 patients) registry data study from the National Marrow Donor Program.[21]

The large study by Flomenberg and colleagues[20] did not detect a difference in engraftment success for patients undergoing mismatched transplants, although another single-center study reported higher risks of engraftment failure for patients receiving transplants mismatched at class I loci at the antigen (low-resolution) level.[22] The risk of rejection was increased, in particular, for recipients homozygous at the mismatched class I locus and for recipients mismatched at more than one locus. A large study of 1298 patients from the Japan Marrow Donor Program found a deleterious effect of class I allelic mismatching on success of engraftment.[23] Single disparities of the HLA-A, -B, -C, or -DRB1 allele were independent risk factors for acute GVHD, and HLA-A and/or HLA-B allele mismatch was found to be a significant factor for the occurrence of chronic GVHD. However, this study did not find an adverse effect of mismatching at the HLA-DR locus on transplant outcomes in contrast to the other studies cited earlier.

DONOR AGE/GENDER

The effects of donor/patient age and gender are primarily on the logistics of the collection procedure, such as the possible need for central venous catheterization for pediatric donors, the presence of comorbid conditions for older donors and patients, and the generally smaller blood volumes of pediatric and female donors. Gender mismatches, especially female donors for male recipients, and older donors increase the risk of GVHD.[24] Donor-selection algorithms will incorporate age and gender into selection criteria.

DONOR HEALTH

Infectious and malignant diseases can be transmitted to the allogeneic/syngeneic transplant recipient, and donors must undergo a comprehensive evaluation before the recipient is conditioned for transplantation.[7,8] Currently, most HSC transplant procedures are performed in the treatment of patients with fatal malignancies who lack other treatment options. In these situations, the recipient, with appropriate informed consent (the donor must first consent to the release of confidential medical information to the recipient), may opt to accept the risk of disease transmission. If time allows, donors with hepatitis may be treated to reduce the risk of disease transmission. Human immunodeficiency virus (HIV) infection is an absolute contraindication to HSC donation. Cytomegalovirus (CMV) is the most common infection likely to be transmitted because of the high incidence of infection in the general population. Fortunately, with current post-transplant monitoring of patients and the availability of effective antiviral drugs, CMV infection has little effect on transplant outcomes. A large retrospective review of 7018 patients seropositive for CMV reported to the European Group for Blood and Marrow Transplantation (EBMT) who received related (5910 patients) or unrelated (1108 patients) found that patients receiving grafts from CMV-seropositive HLA-identical sibling donors had the same survival as patients grafted from seronegative donors.[25] Interestingly, URD recipients receiving grafts from CMV-seropositive donors had an improved 5-year survival (35% vs 27%, an improved event-free survival (EFS; 30% vs 22%), and a reduced transplant-related mortality (49% vs 62%). In patients with chronic myelogenous leukemia (CML), T-cell depletion abrogated the beneficial effect of donor status, suggesting that the effect is mediated through transfer of donor immunity and that for a CMV-seropositive patient, a seropositive donor might be preferable.

RELATIONSHIP

Most patients who are candidates for allogeneic transplantation will lack an appropriate related donor. URD transplantation is facilitated by the large donor registries now totaling more than 10 million potential worldwide donors. However, paradoxically, the advances in high-resolution HLA typing that now can often detect single amino acid differences complicate the search for the ideal HLA-compatible donor. No randomized studies comparing the use of related or URDs are reported. In general, recipients of URD products face higher risks of graft failure, acute and chronic GVHD, and transplant-related mortality.[26]

BLOOD-GROUP MATCHING

The major histocompatibility antigens are located on chromosome 6, and red cells antigens are located on a number of other chromosomes. For this reason, HLA-compatible donors may differ for red cell antigens including ABO, Rh, and other potentially hemolytic antigens. Red cell antigens are not major histocompatibility antigens, and red cell incompatibility does not appear to increase the risk of GVH or HVG reactions. Depletion of red cell and/or plasma from the HSC product will reduce the risks of hemolytic transfusion reactions during HSC infusion, but careful transfusion practices are required to avoid acute or delayed hemolytic transfusion reactions from the infusion of incompatible red blood cells or immunocompetent B lymphocytes. Eventually, recipient red cells and isoagglutinins are replaced by donor type. Red cell incompatibility may be classified into three categories, one in which the recipient has antibodies directed against donor red cells with the potential of acute hemolysis on infusion of the component (major incompatibility), one in which the donor has antibodies against the recipient (minor incompatibility), and one in which both major and minor incompatibility exist (bidirectional incompatibility). Although minor incompatibility rarely causes difficulty during infusion of incompatible plasma, B lymphocytes carried in the component can form increasing titers of isoagglutinins, resulting in a delayed transfusion reaction 7 to

12 days after transplantation. Apheresis devices are commonly used to remove red cells from marrow component for major or bidirectional red cell incompatibility.[27] Red blood cell quantities of 10 mL or less appear, generally, to be tolerable, although no lower limit of red cells exists below which clinical reactions will not occur. Secondary processing of a PBSC component collected by the same technology used for the depletion of red cells from marrow grafts and already containing low quantities of red cells is not required. The persistence of donor isoagglutinins directed against donor red cell antigens will prolong the time to red-cell transfusion independence, and individual patients requiring several years of red-cell support have been reported. Administration of erythropoietin or attempts to remove donor isoagglutinins by plasmapheresis are usually ineffective. Elimination of donor B cells by administration of rituximab or donor lymphocytes (resulting in GVHD) are more likely effective. Minor ABO incompatibility can result in delayed transfusion reactions that may be fatal if appropriate blood-transfusion support (avoiding the infusion of donor-type red cells) is not initiated before the transplant. Two case reports of severe red cell hemolysis after allogeneic PBSC transplantation have been reported. In the first, transfusion support before the event was not described.[28] The second patient received recipient-type red cells on day 7 after transplantation,[29] which is the point at which donor-derived isoagglutinins will be increasing in the recipient. Although both authors discussed the much greater numbers of B cells in PBSCs compared with BM products as a possible factor in these events, it is not clear from these reports that delayed-type transfusion reactions will be more likely or of greater severity in PBSC recipients. The risk of delayed-type reaction may be ameliorated by the use of combination post-transplant immunosuppressive regimens. The Seattle transplant program, for example, found no delayed transfusion reactions in a large retrospective review of patients undergoing PBSC transplantation and who received the two-drug immunosuppressive regimen of cyclosporine and methotrexate.[30]

Syngeneic Donors

Syngeneic HSC transplantation avoids the risk of tumor reinfusion that may complicate autologous transplantation and also avoids the immunologic complications (and benefits) of allogeneic transplantation. Few reports exist of syngeneic transplantation for the treatment of malignant diseases, but the published series, in general, describe a lower risk of relapse compared with autologous transplantation. One review of large transplant databases identified 89 NHL patients who received syngeneic transplants and compared these patients with NHL patients who received allogeneic (T-cell depleted and T-cell replete) or autologous (purged and unpurged) transplants. No significant differences in relapse rates were observed when results of allogeneic transplantation were compared with those of syngeneic transplantation for any histology. However, patients who received unpurged autografts for low-grade NHL had a fivefold ($P = .008$) greater risk of relapse than did recipients of syngeneic transplants, and recipients of unpurged autografts had a twofold ($p = .0009$) greater relapse risk than did patients who received purged autografts.[31] A comparable retrospective study that compared 25 patients with multiple myeloma who received BM grafts ($n = 24$) or PBSCs ($n = 1$) from twin donors to 125 patients who underwent autologous transplantation, and 125 who underwent allogeneic transplantation described no difference in achieving complete remission, but a trend to better overall survival (OS; 73 vs 44 months) and significantly better progression-free survival (72 vs 25 months) for the syngeneic recipients.[32] Syngeneic transplantation requires the administration of dose-intense conditioning and is not appropriate in the setting in which an immunologic response to the underlying disease is required for optimal transplant outcome.

Pediatric Donors

PBSCs and marrow can be collected from pediatric donors, including infants. The special challenges of the pediatric donor arise from the smaller blood volume of the donor, the need for venous catheters for blood access if apheresis is to be used, and the management of a patient who may be unwilling or unable to rest quietly for the period of collection. It is especially important in management of the pediatric PBSC donor (or patient) that timing of apheresis be optimal to minimize the number of procedures required to achieve the desired quantity of PBSCs. Virtually all pediatric patients undergo insertion of a venous catheter adequate for the flow rates expected, although older (older than 12 years) patients may tolerate vein-to-vein procedures.

Selection of Product

PBSCs have virtually replaced BM as the HSC source for autologous transplantation and are widely used for allogeneic transplantation. The ease of collection and the rapid engraftment kinetics of PBSCs compared with BM are widely recognized. Median times to achieve an absolute neutrophil count (ANC) greater than 500 per microliter are typically about 11 to 14 days, and platelet recovery is even faster.[33–35] The more rapid engraftment kinetics for recipients of PBSCs have been confirmed in a number of phase III studies involving either autologous or allogeneic HSC transplantation (Table 58–2). This effect is not limited to HSCs collected from the peripheral blood, because cytokine administration to the patient or donor before marrow harvesting will also increase the number of HSCs collected and result in quicker hematologic recovery.[36–40]

Disadvantages to the use of PBSC components as a source of HSCs for autologous or allogeneic transplantation include the usual need for multiple days of collection (especially for autologous transplantation), the current need for sophisticated flow-cytometric analysis of the components (or hematopoietic cell cultures) to ensure adequacy of HSC content, the inability to collect adequate components from all patients and donors, the risks associated with administration of hematopoietic cytokines and the apheresis procedures, the risks of infusion if the components are cryopreserved, and a possibly higher risk of GVHD or the occurrence of GVHD that is more difficult to control (see Table 58–2).[41–43]

Although GVHD prophylaxis with post-transplant administration of methotrexate will slow engraftment, the kinetics of engraftment for the allogeneic PBSC recipient is similar to that experienced by the autologous PBSC recipient. After multiple phase I and II studies of allogeneic (or syngeneic) PBSC transplantation confirmed the feasibility of this technique,[44–51] at least 11 phase III studies comparing PBSC and marrow transplantation in the related donor setting were published.[52–58] A meta-analysis of 9 of these trials described a lower relapse rate and improvements in overall and disease-free survivals (DFSs) after PBSC transplantation for patients with advanced hematologic malignancies,

although at the cost of a significant risk of extensive chronic GVHD.[59] Multiple studies suggest that chronic GVHD may be more common after PBSC transplantation or may be more difficult to control.[41–43,57] However, treatment-related mortality (TRM) rates may also be lower and leukemia-free survival rates higher with blood stem cell transplants in patients with advanced leukemia (acute leukemia in second remission or CML in accelerated phase) but not in early leukemia (acute leukemia in first remission or CML in chronic phase).[44] The reports of improved survival for patients who undergo PBSC transplantation may, similarly, be particular to transplant regimens or patient selection.

Umbilical cord blood (UCB) is a rich source of HSCs, leading to use as a source of stem cells for transplantation in both adults and children. The major limitation of UCB is the small quantity of cells collected. Advantages are the immediate availability of units, a lower risk of GVHD, and the ability to use mismatched units without a prohibitory increase in transplant complications. Multiple large series of both pediatric and adult transplants using UCB have been reported. In general, as with other sources of HSCs, outcomes of transplantation reflect patient characteristics, with lower survival probabilities for patients with advanced diseases or poorer performance status at time of transplantation. The easy availability and the lack of risk to a donor of an already collected UCB unit promote the treatment of patients who may not be able to wait for identification of an unrelated or related marrow donor or who appear for transplantation with advanced diseases and significant comorbidities. In the multicenter Cord Blood Transplantation (COBLT) study of 34 adult patients, 94% of patients were classified as poor risk according to National Marrow Donor Program criteria, and 4 died before transplantation. The probability of survival to 180 days after transplantation, the primary end point of the study, was 30%, and only two patients survived over the long term.[60] In contrast, a case-controlled series comparing the outcome of adult patients receiving UCB products matched at five of six (34 patients) or four of six (116 patients) loci to recipients of marrow with no (367 patients) or one antigen mismatch (83 patients) treated at multiple centers described 2-year survival probabilities of 20% for recipients of mismatched marrow, 26% for recipients of UCB, and 35% for recipients of HLA-matched marrow ($P < .001$).[61] In this study, however, the survival probability did not differ for recipients of mismatched marrow or UCB products. A similar case-controlled study of 98 adult UCB recipients (6 receiving 6/6 matched products) and 584 HLA-compatible marrow recipients reported 2-year survivals probabilities of 36% and 42%, respectively ($P = .08$) with nonsignificant differences in subgroups classified by diagnosis or stage of disease at the time of transplantation.[62] These data regarding the differing outcomes for different stem cell sources require that transplant programs establish algorithms for selection of an HSC source depending on patient characteristics and treatment plan.

Cell Dose

Cell dose is an important predictor of transplant outcome for both autologous and allogeneic transplantation. An early study of patients undergoing allogeneic transplantation reported higher risks of engraftment failure for patients receiving less than 3×10^8 nucleated BM cells per kilogram, but this was a study of patients with aplastic anemia who received only methotrexate for postgrafting immunosuppression.[63] It is now recognized that successful establishment of donor cell chimerism is a complex interplay of pre- and post-transplant suppression of the host immune system, the dose of HSCs and accessory cells (including donor lymphocytes) contained in the graft, and HLA compatibility between donor and host. HLA-mismatching, T-cell depletion, and less-intensive (less-immunosuppressive) conditioning regimens all increase the risk of graft failure. Autologous transplantation does not present a likely risk of engraftment failure if HSC product viability is maintained during postcollection processing and storage. Instead, the speed of hematologic recovery is related to the quantity of HSCs reinfused, with initial studies demonstrating an exponential relation between cell dose and engraftment speed.[64] Lower doses of CD34+ cells appear satisfactory for nonablative regimens.[65,66] For example, Bokemeyer and colleagues.[65] infused 0.9×10^6 CD34+

cells per cycle for patients treated with high-dose ifosfamide and doxorubicin. Despite an overall doubling of the ifosfamide dose in this phase I study, the median times between cycles did not progressively increase, indicating that adequate marrow stores were maintained. For marrow-ablative regimens, increasingly higher CD34+ doses results in greater likelihood of rapid recovery of peripheral blood counts.[67] Patients who receive a dose of CD34+ cells above an undefined threshold will engraft. At lower doses of CD34+ cells, considerable heterogeneity in engraftment speed is found, especially for platelet recovery, with some patients experiencing quick engraftment despite low doses of PBSCs. As the dose of CD34+ cells increases, the engraftment speed becomes more consistent for the population studied, although the median days of cytopenia are minimally affected in the dose ranges usually administered.[68,69] Several investigators showed more consistently rapid granulocyte and platelet engraftment for recipients of products containing a quantity of CD34+ cells above a dose of about $2–3 \times 10^6$ per kilogram recipient weight.[67,69–71] Importantly, the duration of aplasia predicts the incidence of peritransplant mortality after autologous or allogeneic transplantation.[72]

Similarly, the cell dose is a predictor of outcome for patients undergoing allogeneic (or syngeneic) transplantation.[72–76] A study of 905 patients undergoing BM transplantation from related ($n = 770$) or unrelated ($n = 135$) donors stratified patients in three groups ranging from fewer than 2.4 to more than 5×10^8 nucleated cells/kg and reported that the recipients in the highest group had significantly higher platelet and higher white blood cell (WBC) counts both early and late after transplantation as compared with other patients.[76] The actuarial 5-year transplant-related mortality, OS, and DFS significantly favored patients receiving grafts with higher cell doses. The cell-dose effect was more pronounced in patients older than 30 years, with advanced disease, with a diagnosis of CML, and with alternative donors (other than HLA-compatible siblings). Nucleated cell count is a poor surrogate for HSC content, and similar studies reported an association between CD34+ cell dose and outcome of allogeneic transplantation with either marrow or PBSCs.[77]

Accessory cells contained in the graft also appear to affect the outcome of transplantation in both autologous and allogeneic transplantation. The dose of lymphocytes and the kinetics of lymphocyte recovery after autologous transplantation predicts the probability of disease relapse.[79,80] The quantities of natural killer cells (NK cells), T-lymphocyte subsets, and dendritic cells have been correlated with the risks of GVHD and disease relapse after allogeneic transplantation.[80,81] The ability to manipulate the quantities or function of various cell populations in the HSC graft to improve the outcome of transplantation remains an area of active research.[82] For example, various studies suggest that G-CSF priming changes the cytokine response of lymphocytes contained in the PBSC product,[83] may decrease the risk of acute GVHD,[84] and may increase the graft-versus-leukemia effect.[85] The potential influence of these changes in outcome of allogeneic (or autologous) transplantation is not clear.

Selection of Transplant-Conditioning Regimen

The infusion of HSCs allows the administration of a dose-intense, myeloablative regimen without concern for the effects on hematopoiesis. The efficacy of dose intensity is demonstrated by randomized trials of autologous transplantation for diseases such as multiple myeloma,[86] Hodgkin's disease (HD),[87] and NHL[88]—these trials illustrate that dose-intense therapy is more effective than available nontransplant regimens delivered in multiple cycles over time.

Autologous (and syngeneic) HSC transplantation lacks the immunologic graft-versus-disease (GVD) effect of allogeneic transplantation and cures diseases through the administration of dose-intensive regimens. Therefore, the conditioning regimen used should include drugs that are effective in the treatment of the particular malignancy and, ideally, induce minimal nonhematopoietic organ damage at the myeloablative doses used for transplantation. Immunosuppression is not required for engraftment of autologous HSCs. Some regimens, such as high-dose melphalan for the treatment of patients with multiple myeloma and carmustine (BCNU)-based regimens for the treatment of lymphoma, are commonly used based on the results of multicenter phase III studies showing the tolerability of these regimens. However, the relative efficacy of different conditioning regimens in the treatment of a particular disease has not been studied in large randomized studies. Relapse is the major cause of failure of autologous HSC transplantation and novel techniques to deliver yet more intensive conditioning regimens continue to be explored. One example of this is the addition of radiolabeled antibodies to a chemotherapy or total-body irradiation (TBI)-based regimen to target specifically areas of tumor while sparing radiation-sensitive organs such as the liver, lung, and kidney.[89] Press and colleagues.[89] added 20 to 27 Gy of ^{131}I-labeled anti-CD20 antibody to a conditioning regimen of etoposide (20 mg/kg) and cyclophosphamide (CY; 100 mg/kg) and reported a 77% CR rate and a 68% 2-year probability of progression-free survival (PFS) for patients with relapsed NHL. The two-year PFS was almost double that previously experienced (36%) by similar patients treated with chemotherapy alone. Similar attempts to target therapy to the tumor and increase the intensity of the conditioning are being investigated in allogeneic transplantation.[90]

Allogeneic transplantation differs in the need to achieve adequate immunosuppression of the patient to permit the establishment of donor-cell chimerism, but also in the beneficial effect of the immunologic GVD effect that occurs. The regimen-related (nonhematologic) toxicity is greater after allogeneic transplantation, possibly because of the need for immunosuppressive regimens but also because of GVHD and opportunistic infections. The GVD effect of allogeneic transplantation, however, also allows the use of lower-intensity conditioning regimens for older patients or patients with comorbid conditions that would otherwise preclude transplant-based therapy.

Dose-Intense Regimens

TBI became the primary component of myeloablative conditioning regimens because of its efficacy in the treatment of hematologic malignancies, its ability to treat sanctuary sites of disease such as the central nervous system (CNS), and (for allogeneic transplantation) its immunosuppressive effects. TBI is usually combined in sequence with chemotherapy agents such as CY. The nonhematopoietic toxicities of TBI are reduced by fractioning the dose over several days, allowing higher treatment doses. Increasing the total dose of TBI decreases the risk of relapse but increases the risk of transplant-related complications[91]; often, these effects are offsetting, and event-free survival remains the same.[92–94] The

primary dose-limiting toxicities of TBI include pneumonitis, veno-occlusive disease of the liver, renal impairment, and mucositis. Other attempts to develop regimens with greater tumoricidal effects included the addition of a third agent such as busulfan or etoposide, but again with increased regimen-related toxicities.[95,96]

Busulfan-based regimens were developed as alternatives to TBI-based regimens for the treatment of patients who had received prior dose-limiting radiotherapy, to avoid the effects of TBI on growth and development in children, and to eliminate the difficulty in scheduling patients to the limited number of radiation machines available. Initially, one of the limitations in the use of busulfan was the lack of an intravenous preparation, and wide variation in plasma levels with consequent effects on regimen-related toxicities such as hepatic veno-occlusive disease, failure of engraftment, and relapse of disease.[97–100] Close monitoring of plasma busulfan levels with adjustment of dose reduces the risks of treatment failure, as does the recent availability of an intravenous formulation of this drug.

A number of retrospective analyses and prospective phase III studies compared the outcomes of transplantation using busulfan or TBI-based regimens in allogeneic transplantation.[101–104] One review of four such studies conducted in the treatment of patients with CML or acute myelogenous leukemia (AML) found no statistically significant difference in survival or DFS for patients with CML, with a nonsignificant improvement in survival for patients with AML treated with the TBI regimen.[104] CML patients who received the TBI-based regimen had an increased risk of cataract formation, and patients treated with the busulfan-based regimen had an increased risk of irreversible alopecia. Other late complications occurred equally after both conditioning regimens. Chronic GVHD was the primary risk factor associated with late pulmonary disease and avascular osteonecrosis.

A number of studies explored the addition of agents to protect against nonhematopoietic toxicities of the dose-intense conditioning regimens. This can be as simple as having a patient "chew" ice during the infusion of a single dose of melphalan, which is effective in protecting against oral mucositis because of the quick elimination of this drug from the plasma. Amifostine has been used as a cytoprotective agent in a number of studies, with conflicting results.[105,106] Kerotinocyte growth factor was recently approved for prophylaxis of patients undergoing autologous HSC transplantation based on the results of a phase III study showing a reduction in mucositis.[107]

Reduced-Dose Regimens

Allogeneic transplant recipients benefit from the immunologic GVD effect that develops with establishment of hematopoietic chimerism. Thus control of disease does not result only from the administration of a dose-intense regimen, and nonmyeloablative regimens have been developed for patients ineligible for myeloablative conditioning because of age or comorbid conditions. The primary requirement in developing a reduced-intensity regimen is the need to achieve adequate immunosuppression to permit the development of hematopoietic chimerism. Storb and others[108–111] proposed that the HVG reaction leading to HSC rejection and the GVH reaction could both be modified by an appropriate immunosuppressive regimen administered after transplantation, allowing a reduction in the intensity of the pretransplant conditioning regimen. In a series of canine followed by human trials, this group demonstrated the ability to achieve durable donor cell engraftment with low levels of TBI (2 Gy given in a single fraction) if high concentrations of cyclosporine and mycophenylate mofetil were maintained after transplantation. Engraftment success was improved subsequently with the addition of the purine analog, fludarabine. Again, a variety of regimens are available, including combinations of fludarabine with melphalan and fludarabine with busulfan.[112–114] These regimens can pose less immediate risk of regimen-related toxicities[115,116] and open the option of combining in tandem dose-intense regimens with autologous support (for optimal cytoreduction of the tumor) followed by allogeneic transplantation by using a reduced-intensity regimen (to induce a GVD effect).[115,117,118] For example, a study of tandem autologous transplantation using dose-intense melphalan conditioning followed several months later by allogeneic transplantation using conditioning with a single fraction of TBI reported median days of neutropenia, thrombocytopenia, and hospitalization of none.[117] Comparative studies of myeloablative and reduced-intensity regimens have not been reported, but patients with advanced malignancies may require the increased cytoreduction of the dose-intense regimens for optimal results.[119]

HEMATOLOGIC RECOVERY AFTER HEMATOPOIETIC STEM CELL TRANSPLANTATION

HSC engraftment encompasses two concepts: recovery of hematopoietic and immunologic function of the BM (e.g., yes or no), and the rate at which this recovery occurs (e.g., time to achieve a particular milestone of engraftment). Delay in or failure of sustained engraftment after administration of a myeloablative-conditioning regimen greatly increases the morbidity and cost of the treatment and may result in the death of the patient.[72] Engraftment is a complex interplay of donor, host, and HSC-component characteristics. Engraftment failure can occur as a result of inadequate HSC quantity from poor collection or loss in postcollection processing, or because of inadequate host support of the infused cells,[120] post-transplant events or medications, or the immunologically mediated rejection of the allogeneic donor's cells. Failure of engraftment is a very rare complication of autologous or syngeneic HSC transplantation and is likely only with poor preservation of HSCs after collection. For allogeneic transplants, the risk of engraftment failure is proportional to the disparity between donor and recipient for HLA and minor transplant antigens, occurring more commonly in URD transplantation than in sibling donor transplantation, and for mismatched in comparison with HLA-matched transplants. The risk of engraftment failure is also increased by the removal of T lymphocytes from the marrow inoculum because of the loss of the GVH effect mediated by donor immunoreactive cells.[121] This risk of immunologically mediated rejection can be reduced by increasing the intensity of the pretransplant conditioning regimen to suppress the HVG reaction,[122] such as with increased doses of TBI, but with increased regimen-related toxicity as well. The HVG reaction can also be overcome by increasing the quantity of HSCs in the inoculum, a technique made feasible for human transplantation by the availability of PBSCs that can be used in conjunction with marrow cells.[122] Studies in dogs and humans demonstrated the feasibility of increasing

the intensity of the post-transplant immunosuppression to offset a weaker conditioning regimen.[108]

Delayed engraftment has a deleterious effect on transplant outcomes after either autologous or allogeneic transplantation. In an analysis of duration of severe neutropenia and risk of death in 2276 patients after marrow transplantation, the risk ratio for patients still neutropenic between days 10 and 14 remained close to 1.0, indicating that the risk of death before day 100 for patients with an ANC less than 100 per microliter was similar to that for patients who achieved an ANC ≥100/μL during this time.[73] However, between day 15, when 38% of patients had an ANC less than 100 per microliter, and day 26, when 3.8% of patients had an ANC less than 100 per microliter, the risk ratio showed an overall upward trend, indicating that patients with an ANC less than 100 per microliter had a higher risk of death before day 100 than did those with an ANC ≥100/μL. Similar studies described an adverse correlation between persistent thrombocytopenia and outcomes of allogeneic transplantation.[26,123]

Administration of hematopoietic growth factors may speed engraftment after allogeneic or autologous transplantation. Randomized studies of sargramostim or filgrastim administration after autologous transplantation demonstrated that these hematopoietic cytokines speed granulocyte recovery, may decrease the morbidity of the transplant procedure, and may be associated with a smaller probability of relapse.[124–126] Hematologic recovery after allogeneic transplantation is similarly hastened,[127] but this fact has not consistently translated into earlier hospital discharge or reduced transplant cost because mucositis and other complications of transplantation, not blood cell recovery, are often the primary reasons for continued hospitalization. Assessment of chimerism is important in evaluating poor marrow function after allogeneic HSC transplantation. A decrease in peripheral blood counts could indicate HVG-mediated rejection of the graft or early relapse after transplantation or could be a result of post-transplant events such as GVHD or viral infection. Documentation of stable persistence of donor cells will help discriminate between these possibilities. It is also important that sustained chimerism be demonstrated if infusion of donor T cells is to be used in the treatment of disease relapse after transplantation.[128] The level of donor-host chimerism after allogeneic transplantation is currently demonstrated through the detection of sex chromosomes by using fluorescent in situ hybridization (FISH) techniques or, for same-gender donor-patient pairs, through evaluation of single-nucleotide tandem repeats (STRs) by using molecular analysis techniques. Obviously, these studies are of no value in assessing engraftment after autologous or syngeneic transplantation.

Much of the emphasis in transplantation has been on myeloid engraftment, because initial patient survival depends on recovery of phagocytes and, to a lesser extent, platelets. However, severe immunosuppression is also a consequence of both allogeneic and autologous BM transplantation, resulting from damage to normal barriers such as skin and mucosal linings, loss of phagocytic cells, loss of lymphoid function, and the use of immunosuppressive regimens to prevent or treat GVHD. Lymphoid reconstitution may take months, and even longer, if GVHD occurs. Recoveries of both B- and T-lymphoid function appear to recapitulate ontogeny, with lymphoid subpopulations recovering at different rates.[129,130] Recovery of lymphoid populations (in the absence of GVHD) is similar in allogeneic, syngeneic, and autologous transplantation, although ex vivo purging of T or B cells can delay recovery of specific subpopulations removed by the purge procedure.[131–133] Opportunistic infections occur commonly until host immunity is recovered. Infections are an especially common cause of both morbidity and mortality for transplants complicated by GVHD because of the delay in recovery of immune function caused by this disease and its treatment. Fungal and viral infections commonly occur in association with acute GVHD and its treatment; sinusitis, otitis, and pneumonia are common complications of chronic GVHD.[134] Administration of immunoglobulin (Ig) supplementation to patients with low IgG levels can prevent some of these infectious complications.[135] Reconstitution of dendritic cell function may also predict post-transplant outcomes.[136]

COMPLICATIONS OF HEMATOPOIETIC STEM CELL TRANSPLANTATION

Patients who undergo HSC transplantation face a series of complications arising from the underlying disease, previous treatments that may have been administered, the conditioning regimen used for transplantation, the supportive procedures including antibiotic administration and blood-component transfusions, and (for recipients of allogeneic cells) the immunologic complications of transplantation. Transplantation is given, usually, with curative intent, and the proper management of the transplant recipient includes lifelong monitoring for such complications. The early complications associated with the treatment regimen ("regimen-related toxicities") usually occur within the first 3 months after transplantation. Long-term complications such as the osseus or ocular complications of transplantation may not be detected until several years after treatment. Although patients may achieve a cure of the underlying disease with HSC transplantation, these patients face a higher mortality rate than the general population. One study evaluated the mortality rate of 6691 patients listed in the International Bone Marrow Transplant Registry who were alive and free of their original disease 2 years after allogeneic BMT.[137] Mortality rates in this cohort were compared with those of an age-, sex-, and nationality-matched general population. For these patients, the probability of living for 5 more years was 89%. For patients with a diagnosis of aplastic anemia, the risk of death by the sixth year after transplantation did not differ significantly from that of a normal population. However, mortality remained significantly higher than normal among patients who underwent transplantation for acute lymphoblastic leukemia or CML and through the ninth year among those who underwent transplantation for AML. Recurrent leukemia was the chief cause of death among patients who received a transplant for leukemia, whereas chronic GVHD was the chief cause among those who received a transplant for aplastic anemia. However, most patients who undergo allogeneic transplantation enjoy good health after transplantation. One study evaluated 798 recipients of BM transplants (477 adults, 321 children) from 43 European centers who were alive more than 5 years after transplantation.[138] Fifty-five of these patients died more than 5 years after transplantation, and the actuarial mortality was 8% at 10 years and 14% at 15 years. The leading causes of death were disease recurrence (21 patients), chronic GVHD with complicating infections and lung disease (11 patients), secondary cancer

(8 patients), and the acquired immunodeficiency syndrome (AIDS) (5 patients). The clinical performance was normal (Karnofsky score, 100%) or minimally reduced (Karnofsky score, 90%) in 93% of patients; 89% of patients resumed full-time work or school. Factors associated with poorer quality of life include older age at time of transplantation, presence of long-term sequelae of the treatment, and presence of chronic GVHD.

Infectious Complications of Hematopoietic Stem Cell Transplantation

HSC transplantation predisposes to a unique spectrum of infectious complications as a result chemotherapy damage to host defenses and the immunologic consequences of this treatment. The risk of and type of infection vary over time after transplantation and also for donor type (autologous vs allogeneic). Bacterial infections predominate in the early post-transplant period when the absolute neutrophil count is less than 100 per microliter, and the mucosal and skin barriers are most compromised. The duration and depth of neutropenia independently predict the risk of infection in this the early recovery phase.[139] The majority (70%) of the bacterial pathogens are gram-positive species, with the gram-negative incidence decreasing significantly within the past 20 years. In the mid-recovery phase beginning immediately after engraftment when profound depression of cellular and humoral immunity occurs, viral pathogens, especially CMV, are the major causes of infections. Invasive fungal infections (IFIs)—*Aspergillus*, *Candida* spp.—are increasingly recognized as the major causes of death in allogeneic SCT (ASCT) with an overall incidence of 8% to 15%. This incidence has been correlated with T cell–depleted or CD34-selected HSC products, acute and chronic GVHD, treatment with corticosteroids, secondary neutropenia, CMV infection, and respiratory virus infection.[139]

Pretransplant diagnosis does not appear to predict different risks of bacterial infections after transplantation. Auner and colleagues[140] analyzed data from 114 patients who had undergone high-dose chemotherapy and autologous HSC transplantation in the treatment of AML, NHL/HD, and MM, and found no differences with respect to the type or incidence of infections despite a longer median duration of neutropenia in the leukemia and lymphoma populations. In contrast, the choice of preparative regimen may independently influence the risk of infection. In a study published by Ketterer and associates[141] of 277 patients, fludarabine or TBI-based preparative regimens were associated with a higher risk (26%) of late infections, with viral infections, mainly varicella zoster virus (VZV) and pneumonia the main etiologies. Junghanss and coworkers[142] compared the infectious complications of allogeneic transplantation by using either myeloablative or reduced-intensity conditioning (RIC) regimens. Patients undergoing a reduced-intensity regimen experienced a shorter duration of neutropenia and fewer episodes of bacteremia during the initial 30- and 100-day periods (9% vs 27%, $P = .01$; and 27% vs 41%, $P = .07$, respectively) after transplantation. However, the rates of invasive aspergillosis during the first year after transplantation were the same for both groups, illustrating the effects of GVHD and its treatment on the risk of infection after allogeneic transplantation. Multivariate analysis identified neutropenia and CMV disease as the major factors associated with bacteremia and aspergillus infection.

Although transplant-related mortality continues to decrease as a result of improved transplant techniques, supportive care, and judicious patient selection, infective death rates continue to be significant. In a landmark special report by Gratwohl and colleagues[143] of the EBMT, data from 14,403 patients with a diagnosis of leukemia undergoing transplantation with reduced-intensity conditioning regimens were retrospectively analyzed to determine the causes of post-transplant death. They reported an 11% infective death rate. Of the 597 deaths from infection, 36%, 31%, 28%, and 5% were attributed to bacteria, viruses, fungi, and parasites, respectively. Remarkably, even though the cumulative incidence of death from infection decreased over time, the relative contributions remained stable. Bacterial infections predominated during the initial 3 months after transplantation, with approximately 50% of all infections occurring in this period. The risk of infectious death diminished with time after transplantation, with 25% of infectious deaths occurring in the first 2 months, 25% after 7 months, and 10% beyond 1 year, and the majority of deaths occurring after initial hematologic recovery. They reiterated that the pretransplant factors associated with infectious death were advancing age and T-cell depletion. An advantage was noted for patients undergoing PBSC transplantation with respect to all infectious etiologies. Inexplicably, they reported a higher incidence of death from viral infections among female patients. They postulated that this phenomenon may be as a result of transmission of respiratory syncytial virus (RSV) and VZV from children. The conclusion was that delayed immune reconstitution is probably more important than marrow hypoplasia as a factor contributing to infectious death.

Reports have also been published detailing the infectious complications and mortality after unrelated donor cord blood transplant (UCBT). Because of the different kinetics of myeloid and lymphoid recovery after UCBT, there was a higher rate of early bacterial blood stream infections. Absence of grade II-IV GVHD was associated with higher incidence of *VZV* reactivation but lower incidence of CMV antigenemia and disease. However, the major cause of infectious mortality was multiresistant *Acinetobacter* spp.[144,145]

The incidence of postengraftment invasive aspergillosis is increasing. A large single-institution study of 1682 patients undergoing allogeneic transplantation identified older patient age and diagnosis as risk factors for early infection.[146] Transplantation of PBSCs conferred protection against early (<40 days) infection compared with the use of BM. Factors that increased risks for later (beyond 40 days) infection included receipt of T cell–depleted or CD34-selected stem cell products, receipt of corticosteroids, neutropenia, lymphopenia, GVHD, CMV disease, and respiratory virus infections. Very late infection (>6 months after transplantation) was associated with chronic GVHD and CMV disease.

Regimen-Related Toxicities

Early Complications

The patient undergoing dose-intense therapy with autologous HSC transplantation experiences a period of marrow hypoplasia that can persist for days or weeks. During this time, the patient will require antibiotic and blood component support, but death from infection or hemorrhage is uncommon. Nonhematopoietic toxicity that is common but not life threatening may include alopecia and varying degrees of mucositis with concomitant mouth pain, inanition, and diarrhea. Rarely,

mucositis compromises the safety of the airway, and intubation of the patient is temporarily required for airway protection. Serious organ toxicity includes hepatic venocclusive disease (from high-dose regimens in general), interstitial pneumonitis (e.g., BCNU induced), cardiomyopathy (e.g., CY induced), and hemorrhagic cystitis (e.g., CY induced). The risk of nonhematopoietic toxicity increases for older patients and for patients who previously received intensive chemotherapy regimens. For these patients, reduction of dose of the transplant conditioning regimen may be appropriate, but at possibly increased risk of relapse of disease.

Mucositis and gastrointestinal toxicity are the most prevalent early nonhematologic complications of dose-intense therapy, usually occurring within the first 10 to 14 days after transplantation. In one study of 202 recipients of high-dose therapy and autologous or allogeneic stem-cell rescue, a diagnosis of leukemia, use of TBI, allogeneic transplantation, and delayed neutrophil recovery were associated with increased oral mucositis and longer parenteral nutritional support.[147] Administration of keratinocyte growth factor may reduce the incidence and severity of mucositis. A randomized, placebo-controlled study of palifermin in patients undergoing dose-intense therapy with autologous HSC support reported that the incidence of oral mucositis of World Health Organization (WHO) grade 3 or 4 was 63% in the palifermin group and 98% in the placebo group ($P < .001$). Furthermore, among patients with this degree of mucositis, the median duration of mucositis was 6 days (range, 1 to 22 days) in the palifermin group and 9 days (range, 1 to 27 days) in the placebo group. As compared with placebo, palifermin was also associated with significant reductions in the use of opioid analgesics and the incidence of use of total parenteral nutrition.[148]

The incidence of hepatic venocclusive disease (VOD) ranges from 5% to 50%. It is defined as a conditioning regimen-related and dose-limiting toxicity and is significantly more prevalent after allogeneic SCT compared with autologous SCT, and with the use of dose-intense compared with reduced-intensity conditioning regimens. The factors predisposing to its incidence are the transplant procedure itself, use of TBI as part of the conditioning regimen, use of methotrexate for post-transplant immunosuppression, and pre-existing or antecedent hepatic dysfunction. Clinical signs suggestive of VOD are tender hepatomegaly, noncardiogenic weight gain, and hyperbilirubinemia, which usually occur within the first 3 weeks after transplantation. Overall mortality ranges from 20% to 50% in various series, reaching 98% for patients with severe disease.[149] Oral busulfan has been the standard in many myeloablative regimens since the 1970s. However, its use is productive of increased VOD secondary to the hepatic first-pass effect, unpredictable absorption kinetics, and variable bioavailability, with sinusoidal obstruction as the terminal event.[150] With the formulation of intravenous busulfan, the incidence of VOD significantly decreased with no loss of myeloablative efficacy.[151–153] Treatment of VOD is usually best supportive care, although defribotide may be effective.[154]

Late Complications

Avascular necrosis (AVN) of bone is an uncommon but not rare complication of HSC transplantation, with an average time of onset of about 2 years after transplantation. The cause of this complication is not defined, although vasculitis involving intraosseous blood vessels induced by GVHD has been proposed for patients undergoing allogeneic HSC transplantation.[155] Two large retrospective studies have defined risk factors associated with this complication. A multicenter study of 4388 patients, recorded in the Societe Francaise de Greffe de Moelle (SFGM) database, who had undergone a single allogeneic BMT, described 77 patients who developed avascular necrosis, leading to a 4.3% projected incidence at 5 years. Symptoms developed 2 to 132 months after transplantation. A mean of 1.87 joints per patient were affected (range, 1–7 joints), with the hip joint being the most often affected (88% of patients) and 48% of the patients required joint replacement. In univariate analysis, six risk factors were shown to be linked to an increased risk: older age, diagnosis of aplastic anemia or acute leukemia, an irradiation-based conditioning regimen, type of GVHD prophylaxis regimens, and occurrence of acute and chronic GVHD. In multivariate logistic regression analysis, five factors remained significantly associated with an increased risk for developing avascular necrosis: chronic GVHD (odds ratio [OR], 3.52), acute GvHD (OR, 3.73), age older than 16 years (OR, 5.81), aplastic anemia (OR, 3.90), and acute leukemia (OR, 1.72).[156] A case-control study of 1939 long-term survivors who underwent BMT at a single center found 88 who developed AVN after transplantation (an addition eight patients developed AVN before transplant) at a mean of 26.3 months. Post-transplant steroid use was a risk factor for the occurrence of AVN (adjusted OR, 14.4; 95% confidence interval [CI], 2.8–73.2), with the greatest risk associated with those receiving steroids at the time of diagnosis of AVN (adjusted OR, 31.9; 95% CI, 4.4–248.9). No further increasing risk was associated with increasing duration of steroid use. Conditioning with TBI was also associated with the occurrence of AVN (adjusted OR, 3.2).[157]

Cataract formation is a frequent long-term complication of HSC transplantation and is associated with administration of TBI and corticosteroids. A retrospective analysis of 1063 patients from the EBMT registry who were evaluable for survival and ophthalmologic status after transplant for acute leukemia reported an overall 10-year estimated cataract incidence of 50%. In this analysis, factors independently associated with an increased risk of cataract were older age, higher radiation dose rate (>0.04 Gy/min), allogeneic HSC transplantation, and longer-term steroid administration (>100 days).[158]

Bronchiolitis obliterans is a late complication of BMT associated with chronic GVHD and is frequently fatal. One retrospective analysis of 2859 HSC transplantation recipients found no cases of among 1070 autologous transplant recipients.[159] Among the 1789 allogeneic recipients, 47 patients with this pulmonary complication were found, and older ages of recipients and donors and the development of acute GVHD were significantly associated with the development of bronchiolitis obliterans. Among patients with this complication, the 5-year survival from the time of transplantation was only 10% compared with 40% among allogeneic recipients without. Pulmonary failure was the leading cause of death.

The majority of dose-intense conditioning regimens invariably cause gonadal failure, with only a minority of patients able to regain gonadal function after HSCT. Therefore, puberty and menarche are delayed or abrogated completely. For women, ovarian failure is guaranteed in the face of busulfan and or TBI conditioning. Indeed, fertility will already have been seriously compromised by induction and consolidation chemotherapeutic and radiotherapeutic strategies. Despite this, more than 50% of women younger than 26 years will regain ovarian functioning if CY only is used and approximately 10% in patients conditioned with TBI. Clinically recognized pregnancies among women who have received a marrow transplant incorporating TBI are likely to be accompanied by an increased risk of spontaneous abortion. Pregnancies among all women who received

a marrow transplant are likely to be accompanied by preterm labor and delivery of low-birth-weight (LBW) or very LBW (VLBW) babies who do not seem to be at an increased risk of congenital anomalies.[160] However, determination of possible adverse effects of parental exposure to high-dose alkylating agents with or without TBI on children born after transplant requires longer, additional follow-up.

The need for hormone-replacement therapy (HRT) should be investigated for both men and women after HSC transplantation. For female patients unopposed estrogen predisposes to endometrial cancer, whereas combined estrogen receptor (ER) + progesterone receptor (PR) increases the risk of cardiovascular events and invasive breast cancer beginning 2 to 5 years after HSCT. In view of the foregoing management of menopausal symptoms, loss of bone mineral density becomes more important. Individualization of management with informed consent before systemic or topical HRT is recommended. The importance of screening mammography, breast self-exams, and pap smears cannot be overstated.[161] For men, decreased libido, low testosterone levels, and osteopenia mandate the use of HRT, but, as is the case with their female counterparts, scrupulous informed consent and preventive screening for prostate cancer, liver-function test monitoring, and detection of lipid abnormalities are necessary.[162]

Second Cancers after Hematopoietic Stem Cell Transplantation

The development of second cancers, including myelodysplasia or secondary leukemia, is a well-described complication of allogeneic or autologous HSC transplantation.[163–167] Possible explanations include administration of chemotherapy or radiotherapy, prolonged administration of immunosuppressive agents, and chronic irritation of tissues (e.g., lining of mouth) that are target organs of GVHD. A prevalence of myelodysplasia or secondary leukemia appears to exist after autologous transplantation, and this risk may be increased with certain pretransplant agents such as etoposide or TBI.[163] Studies of second cancers after allogeneic transplantation report a variety of nonhematologic malignancies. One series of 1036 patients enrolled into cooperative group transplant trials reported second cancers in 53 patients, with an actuarial incidence of 3.5% at 10 years and 12.8% at 15 years.[168] The rate of new malignant disease was 3.8-fold higher than that in an age-matched control population, with the most frequent malignant diseases being neoplasms of the skin (14 patients), oral cavity (7 patients), uterus (5 patients), thyroid gland (5 patients), breast (4 patients), and glial tissue (3 patients). Malignant neoplasms were more frequent in older patients and in patients with chronic GVHD. A very large study of more than 19,000 patients who underwent allogeneic or syngeneic transplantation also found a higher risk of cancer compared with that in the general population, with the risk increasing to 8.3 times that expected among those who survived 10 years or longer after transplantation.[169] The risk was significantly elevated for malignant melanoma (ratio of observed-to-expected cases, 5.0) and cancers of the buccal cavity (11.1), liver (7.5), brain or other parts of the central nervous system (7.6), thyroid (6.6), bone (13.4), and connective tissue (8.0). The cumulative incidence rate was 2.2% at 10 years and 6.7% at 15 years. In this study, the risk was higher for recipients who were younger at the time of transplantation than for those who were older. Multivariate analyses found an association between higher doses of TBI and a higher risk of solid cancers, and chronic GVHD and male gender were strongly linked with an excess risk of squamous cell cancers of the buccal cavity and skin. An increased risk of solid tumors was also reported by one center after autologous transplantation in the treatment of patients with NHL.[170] In this series of 605 patients, the risk of a nonhematologic malignancy was 10%, with the risk continuing to increase with continued follow-up. The risk of any second cancer was 29%, and a second malignancy was the cause of death for 10% of patients treated. Again, older age was the primary factor associated with the development of a second cancer.

Relapse of Disease after Hematopoietic Stem Cell Transplantation

Relapse of disease is the most frequent cause of treatment failure after autologous or allogeneic HSC transplantation. Factors associated with higher risk of relapse include transplantation at a more-advanced stage of disease, autologous transplantation, absence of GVHD, T-cell depletion of the allograft, and less-intensive conditioning regimen. A small proportion of patients can undergo a second transplant, although the peritransplant mortality is greatly increased with use of a second dose-intense regimen.[171,172] The probability of successful outcome is greater for patients with longer disease-free intervals between transplants. Manipulation of the donor-derived immune system in the allogeneic recipient (cf., GVL effects, described later) may achieve control of disease in a minority of patients.

IMMUNOLOGIC CONSEQUENCES OF HEMATOPOIETIC STEM CELL TRANSPLANTATION

Establishment of hematopoietic chimerism with its attendant GVH reaction has both advantageous and deleterious consequences for the patient undergoing allogeneic HSC transplantation. Acute and chronic GVHD (the clinical sequelae of this reaction) are major causes of both early and late mortality and may result in considerable morbidity if not adequately controlled. However, the GVD benefit of allografting is the justification for the development of reduced-intensity transplant-conditioning regimens and is the primary reason for the lower relapse rate observed after allogeneic compared with autologous transplantation. The mechanisms involved in the development of GVHD and GVD continue to be dissected in both human and animal studies. Similarly, studies are being conducted in an attempt to separate the beneficial GVD from the detrimental GVHD to improve the outcome of allogeneic transplantation. In 1966, Billingham[173] postulated that three requirements must be met for GVHD to occur: the transplanted graft must contain immunocompetent cells, the host must be incapable of rejecting the transplanted cells, and the host must express tissue antigens that are not present in the transplant donor and can be recognized as foreign. GVHD is a much more complex phenomenon, involving cytokine networks as well as a variety of cellular mediators including antigen-presenting cells.

Graft-versus-Host Disease

Acute Graft-versus-Host Disease

The form of GVHD occurring early after transplantation, usually within the first 100 days, is referred to as acute

GVHD. Organs involved include skin, gastrointestinal tract, and liver; involvement of skin is most common, but any organ may be involved either alone or in combination with other tissue targets of immunologic attack. GVHD is a clinical diagnosis with laboratory confirmation. No laboratory studies, including tissue biopsies, are available to confirm or exclude this diagnosis. Skin rash, which is the most common presenting manifestation of GVHD, may also result from an allergic reaction to medication or toxicity from the conditioning regimen. Nausea, anorexia, and diarrhea may result from the conditioning regimen or infectious consequences of transplantation as well as from GVHD. Each of these complications of transplantation more commonly occurs at distinct times after transplantation, simplifying the diagnosis.

In contrast to the simple concepts proposed by Bellingham, the results of murine and human studies now show that acute GVHD (aGVHD) can be considered a three-step process: (1) damage to host tissues from chemotherapy/radiotherapy inducing the secretion of inflammatory cytokines; (2) activation and amplification of donor T cells interacting with host antigen-presenting cells along with increased expression of major histocompatibility complex (MHC) antigens; and (3) target cell apoptosis via both cellular and inflammatory mediators.[174,175]

The risk of developing aGVHD increases primarily with HLA disparity between donor and recipient,[176] but also with increasing age of donor and recipient, gender disparity, and infusion of T cell–replete HSC products. Conditioning with reduced-intensity regimens, with lower regimen-related toxicities to nonhematologic tissues, also results in a lower risk of aGVHD (but not chronic GVHD [cGVHD]), but may also shift the time to initial manifestations of GVHD.[177]

Pharmacologic agents are the mainstay of prophylaxis of aGVHD. Most patients receive a combination of a calcineurin inhibitor (tacrolimus or cyclosporine) along with an antimetabolite such as methotrexate or mycophenylate mofetil (MMF). Randomized studies in related donor and URD transplantation of tacrolimus and cyclosporine showed a lower incidence of aGVHD for recipients of tacrolimus, but no differences in event-free survival, at least for patients with less-advanced diseases.[178,179] Methotrexate is associated with delayed engraftment, mucositis, idiopathic pneumonia syndrome, and other transplant-related complications, prompting the development of other combination regimens such as a calcineurin inhibitor in combination with sirolimus or MMF. In these studies, mucositis was modest, engraftment was prompt, and transplant-related toxicity was modest.[180–182] Other centers reported possible success of reduced doses of methotrexate, although randomized studies have not been conducted.[183] The addition of antithymocyte globulin (ATG) to the conditioning regimen lowers the GVH and HVG reactions because of the persistence of this agent for several days after HSC infusion.[111,186] However, patients treated with ATG may face higher risks of infectious complications including Epstein-Barr virus (EBV)-associated post-transplant lymphoproliferative disorder as a result of the greater immunosuppression achieved.

T lymphocytes are primary mediators of the GVH reaction, and multiple studies have demonstrated lower risks of aGVHD for recipients of T cell–depleted grafts, including large randomized studies.[185] Unfortunately, T-cell depletion increases the risks of engraftment failure and relapse after disease, as a result of the loss of the beneficial effects of the GVH reaction, and long-term event-free survivals are similar for patients receiving T cell–depleted or T cell–replete grafts. Several transplant groups explored depletion of T-cell subsets in attempts to discriminate between the beneficial and deleterious effects of the GVH reaction.[186] To date, no specific technique has shown superiority in clinical studies in humans.

Glucocorticoids remain the standard approach to initial systemic management of clinically significant aGVHD. Patients who fail to respond to initial therapy have a poor prognosis, as additional agents added for control increase the risk of opportunistic infections and other complications. The use of higher doses of corticosteroids, concomitant addition of ATG, for example, have not proven to improve the outcomes of patients who develop aGVHD and should be reserved for patients who are refractory to initial therapy.[187,188] A number of drugs including ATG, pentastatin, switching to tacrolimus from cyclosporine, and newer monoclonal antibodies have shown (limited) activity in the salvage treatment of patients with steroid-refractory aGVHD.[189–191] Extracorporeal exposure of peripheral blood mononuclear cells to the photosensitizing agent 8-methoxypsoralen and UVA radiation (photopheresis) has been shown to be effective in the treatment of selected diseases mediated by T cells, including both aGVHD and cGVHD and is a novel approach to the treatment of patients with steroid-refractory GVHD.[192]

Chronic Graft-versus-Host Disease

Chronic GVHD is the leading cause of late treatment-related deaths among recipients of allogeneic BM and blood transplants. cGVHD resembles autoimmune disorders such as scleroderma, Sjögren syndrome, and primary biliary cirrhosis. Diagnosis is, as with acute GVHD, based on clinical observations with secondary laboratory confirmation (Table 58–3) A falling performance status, progression weight loss, or recurrent infections are usually signs of clinical extensive cGVHD. About 50% of long-term survivors will develop this complication of transplantation at a median of 9 months, and patients must be monitored closely for at least 2 years after transplantation so that appropriate treatment can be initiated before extensive tissue damage develops.

Factors predicting the development of cGVHD again include degree of HLA disparity but also include source of HSCs (PBSC transplantation conveys a higher risk compared with marrow or cord blood transplantation). Patients who develop cGVHD have a higher risk of TRM but a lower risk of relapse as a result of the immunologic GVD effect.[193] T cell depletion may decrease the risk of cGVHD, although this has not been demonstrated in all studies. A randomized study of 404 patients undergoing marrow transplantation from URDs reported similar incidences of cGVHD for recipients of T cell–depleted or T cell–replete grafts; the duration of post-transplant immunosuppression and OS were also similar for the two arms of this study.[196]

Most patients require at least two drugs for treatment of cGVHD. Again, glucocorticoids along with a calcineurin inhibitor are the standard initial treatment. About half of the patients with cGVHD do not achieve a complete remission with first-line therapy. No clear recommendations exist regarding second-line treatments, and a variety of pharmacologic and immunologic techniques have been used. Retransplantation is ineffective, but a single-center report of low-dose thoracoabdominal irradiation described an 82% response rate, with the best responses observed for patients

Table 58–3 **Manifestations of Chronic Graft-versus-Host Disease**

Target Organ	Physical Manifestation	Target Organ	Physical Manifestation
Skin	Erythema Dryness Exfoliation Macular-papular or urticarial rash Pigmentary changes (hyperpigmentation, vitiligo, mottling) Papulosquamous or lichenoid plaques Keratosis Nodules Scleroderma Morphea	Vagina/vulva	Dryness Dyspareunia Strictures or stenosis Erythema Atrophy or lichenoid changes not attributed to ovarian failure
Nails	Ridging Onychodystrophy Onycholysis	Liver	Elevated bilirubin or liver-function tests not resulting from other cause
Hair	Premature graying Thinning scalp hair Alopecia Decreased body hair	Lung	Bronchiolitis obliterans Cough Wheezing Dyspnea on exertion History of recurrent bronchitis or sinusitis
Mouth	Burning Gingivitis Mucositis Ulcers Erythema Striae Dryness Atrophy Lichenoid changes Labial atrophy or pigmentary changes Tightness around the mouth Sensitivity to acidity, strong flavors, heat or cold Tooth decay	GI	Anorexia Nausea Vomiting Diarrhea Malabsorption Weight loss Dysphagia Odynophagia
Eyes	Dryness Burning Blurring Gritty eyes Photophobia Pain		

with fasciitis or oral involvement.[195] Photopheresis has an overall response rate of 50% to 60%, with many patients achieving complete control of this complication of transplantation.[196]

Graft-versus-Leukemia Effect

The chemoradiotherapy regimen used for the treatment of patients is intended to cure the underlying disease, with the HSCs infused merely to rescue the patient from the marrow-lethal toxicity of the regimen. However, it became evident very early that patients who experienced acute or chronic GVHD had a much lower risk of relapse after transplantation than did those without these complications. The potential of the GVD effect is demonstrated by the infusion of unmodified peripheral blood mononuclear cells from the marrow donor for the treatment of relapse after allogeneic BMT. Kolb and colleagues[128] reported the administration of donor lymphocytes to 135 patients with chronic and acute leukemias who relapsed after allogeneic transplantation. Complete remissions were achieved in 73% of patients with CML, but only 29% of patients with AML. None of the patients treated for acute lymphoblastic leukemia (ALL) responded to this treatment, suggesting that this approach is most practical for more indolent diseases. Complications of this therapy include the development of GVHD (41%) and myelosuppression (34%). The number of lymphocytes infused is important in achieving this effect, and it may be possible to induce GVD by using doses of lymphocytes that are less likely to result in GVHD.[197] However, a distinction between the cells responsible for inducing GVD and those causing GVHD has not been found. The delay in response between lymphocyte infusion and the development of a GVD effect suggests that only a minority of the cells infused recognize the tumor cell antigens and must undergo in vivo expansion before a therapeutic effect is achieved. It may be possible to develop cytotoxic lymphocytes in the laboratory, decreasing the delay in effect and possibly increasing the effect in the more rapidly proliferative acute leukemias.[198]

Peripheral blood mononuclear cell components (donor-cell lymphocytes infusion, DLI) collected from donors either with or without treatment with granulocyte colony–stimulating factor (G-CSF) are also effective in the immunotherapy of patients with progressive disease after allogeneic transplantation.[199–201] Patients with low-grade lymphoid malignancies such as CLL or indolent NHL, mantle cell

NHL, and CML have the highest likelihood of response. The results of a survey of 25 transplant programs identified 140 patients who received DLI and reported a CR rate of 60% in patients with CML; response rates were higher in patients with cytogenetic and chronic-phase relapse (75.7%) than in patients with accelerated-phase (33.3%) or blastic-phase (16.7%) relapse, and almost 90% of these patients remained in remission at 2 years after treatment.[202] Complete remission rates in AML and ALL patients who had not received pre-DLI chemotherapy were 15.4% and 18.2%, respectively. Complications of DLI included aGVHD (60%), cGVHD (60.7%), and pancytopenia (18.6%). The development of GVHD after DLI was highly correlated with disease response ($P < .00001$).

Donor immunity can be transferred at least transiently to the host, as demonstrated by delayed-type transfusion reactions to host red blood cells mediated by donor lymphocytes transfused along with the marrow.[203] Adoptive transfer of donor immunity against specific targets can be achieved, but its persistence requires immunization of both the donor and the recipient.[204,205] A clinical utility for such manipulation of the immune system has not yet been demonstrated but is clearly of interest as a technique to prevent post-transplant infections or, possibly, relapse.

DISEASES TREATED

Acute Myelogenous Leukemia

Induction chemotherapy yields complete remission for most patients with AML, but these patients will rapidly relapse if postinduction consolidation therapy is not administered. Randomized studies of consolidation regimens of varying intensity demonstrate that more-intensive regimens will achieve a higher probability of durable remissions. Despite this, even with the administration of several cycles of consolidation therapy, the probability of cure is only on the order of 35%. Cytogenetic status remains the single most important prognostic factor, although other factors can also help in risk stratification.[206]

Because chemotherapy-only regimens achieve disease control for a minority of patients, transplant strategies were investigated to evaluate their relative efficacy. To date no fewer than 16 studies have failed to demonstrate conclusively the superiority of allogenic stem cell transplantation (SCT) over autologous and nontransplant modalities in the consolidative treatment of AML. Indeed, these published reports have been conflicting about the true relative merits of the three modalities. This seems in no small part to be due to the widely disparate treatment regimens used and the number and intensity of consolidation cycles before SCT.

The selection of a postremission treatment plan hinges on multiple factors: the age and performance status of the patient, the number of cycles of treatment required to achieve remission, the pretreatment cytogenetics, and the minimal residual disease (MRD) status.[207,208] Assessment of these prognostic factors and the fact that AML represents an intermediate disease sensitivity to a graft-versus-malignancy effect provides a risk-stratification basis for the implementation of autologous versus allogenic SCT and the timing (CR1 vs CR2) of further consolidation.

In general, autologous BMT has not proven to be more effective than nontransplant intensive consolidation chemotherapy (Table 58–4), although studies reported by Burnett and colleagues[209] and Zittoun and colleagues[210] demonstrated significantly better DFS for recipients of autologous (54% vs 41%) and allogeneic (48% vs 30%) transplantation compared with recipients of chemotherapy, respectively. Therefore, the timing and patient selection are critical because the best results for allogenic SCT have been noted in younger patients in CR1. If a patient in CR1 relapses, then early preemptive allogenic SCT should be undertaken, as opposed to reinduction to CR2. The rationale is that even though CR2 may be achieved by reinduction chemotherapy, the DFS is short with probable early relapse and relentlessly difficult-to-control disease due to increased tumor cell resistance and disease burden.[211]

Table 58–4 Multicenter Randomized Studies Comparing Autologous Marrow Transplantation to Intensive Consolidation Chemotherapy

	Probability of Event-Free Survival (%)		
Investigator	Allogeneic	Auto-logous	Chemo-therapy

Publication of CALGB 8461 has been instrumental in classifying AML patients into low-, intermediate-, or high-risk groups based on the pretreatment cytogenetic status. The t(15;17), t(8;21), inv16, and t(16;16) are the favorable cytogenetic abnormalities, and based on cytogenetic stratification, this good-risk group of patients in CR1 would benefit most from high-dose consolidation chemotherapy as the risks of an SCT outweigh the benefit.[210,213] Indeed the remarkable advances in the treatment of APL with t(15;17) have minimized the role of transplantation in first remission in this subtype.[214,215] Therefore, patients with these abnormalities should be offered ASCT only on relapse or if identified to have molecular abnormalities that predict relapse despite overt good-risk karyotype. To this end, Acute Leukemia French Association (ALFA) centers carried out two consecutive trials considering allogeneic sibling SCT in 92 young AML patients with t(8;21)/inv(16) (core-binding factor [CBF] group) or a normal karyotype (NN group). Sixty-six (66%) achieved CR2. Donor availability was an independent prognostic factor for survival in the patient population as a whole as well as in the CBF subset, but not in NN patients, further supporting this strategy for CBF-AML. The presence of an FLT3 internal tandem duplication (ITD) was found to be the main poor prognostic factor for attaining second CR and survival, mandating earlier consideration of SCT, especially in NN patients.[216] Additionally, Kim and associates[217] published their investigation of AML patients with normal cytogenetics in which a multiple drug resistance (MDR) phenotype was found to be an independent prognostic factor for EFS and OS.

Allogenic SCT has the lowest risk of relapse with the highest TRM. In the unfavorable-risk group, an allogeneic sibling SCT in CR1 would be acceptable, as the outcomes with

chemotherapy alone or with an autologous SCT are dismal.[218] Patients with poor-risk cytogenetics such as trisomy 8, monosomy 5 or 7, and complex cytogenetics merit early ASCT in CR1. Additionally, chromosome 5 and/or 7 abnormalities are indicative of a poor prognosis and the only potential cure for such patients is allogeneic SCT, although data in this context are limited. In a retrospective study between 1983 and 2001 recorded by the Netherlands Stem Cell Transplant Registry (Typhon), OS was 25%. Factors that predicted lower relapse rate and better OS were age younger than 40 years, unrelated grafts, and chromosome 5 or chromosome 7 abnormalities, but not both. The development of GVHD grades II to IV was independently associated with significantly higher TRM albeit similar to patients with a secondary AML and normal cytogenetics. Therefore, although patients with AML with chromosome 5 and/or 7 abnormalities do rather poorly after ASCT, this is the only approach that can achieve a substantial long-term survival and cure in patients with high-risk acute leukemia.[219]

Controversy still centers around the suitability of early matched sibling SCT in CR1 versus at relapse. Approximately 25% of patients in CR1 may indeed be cured, and to subject them to an unnecessarily toxic procedure must be weighed against the specter of relapsed disease with compromised performance status, resistant disease, and increased disease burden. This therefore confirms the importance of pretreatment cytogenetic assessment and post-treatment MRD assays.

For intermediate-risk patients ABMT/ASCT is an appropriate treatment choice and seems to improve outcomes compared with conventional chemotherapy.[220] Autologous SCT has an intermediate risk of relapse and TRM, although its role in CR1 is not obvious, and questions remain about the selection of HSC source, value of ex vivo purging, and timing of transplantation relative to other cycles of postinduction consolidation. Autologous SCT appears to be effective therapy for the patient with AML in second CR, as reported in a number of phase II studies where the survival probabilities of ≥35% are significantly superior to standard chemotherapy regimens.[221]

AML is a disease in which purging of tumor cells may be beneficial because the presence of MRD predisposes to earlier and higher relapse rates. In nonrandomized studies, patients who received marrow cells treated with chemotherapy agents were less likely to relapse after transplantation. Indeed, Osborne and colleagues[222] recently published a study using the WT1 transcript, as a marker of MRD in BM harvests of 24 patients slated for autologous SCT. At median follow-up of 92 months, they reported an relapse-free survival (RFS) of 10.4 months for patients with WTI more than 2000 (high risk) and an as-yet-reached RFS for patients with scores less than 2000 (low risk) ($P < .05$). Similarly, indirect laboratory assessments of purging efficacy suggest a benefit for patients who are treated with an aggressive purging technique. Despite the foregoing, the role of purging has not been proven in randomized studies, nor has it been shown to be of benefit in PBSCT.

However, the change that may have the greatest impact on AML treatment is the advent of reduced intensity or NST.[223] Reduced-intensity hematopoietic cell transplantation (HCT) relies on the GVL effect of the allograft rather than the direct tumoricidal activity of the conditioning regimen. Because of the paucity of any direct antileukemic effect of the conditioning regimens, the truly nonmyeloablative regimens can be used only in patients with low volumes of disease, whereas the reduced-intensity conditioning regimens, which usually contain fludarabine and some alkylating agent, do have direct antileukemia activity and can be used with more-extensive disease.[224] The shortened duration of cytopenias and the minimal mucosal toxicity of the newer reduced-intensity conditioning regimens provide a reasonably safe transplant option for patients 2 decades older than the population that was treated with traditional fully ablative high-dose chemoradiotherapy regimens.[225]

A lack of consensus is found in the literature about the true definition of primary refractory disease with respect to the morphologic criteria and the number of induction regimens required before it is deemed refractory. Nevertheless, TRM occurs and risk of relapse with a 5-year EFS of only 10% to 20%. Factors to consider before implementing allogeneic transplantation for primary refractory AML are those that are critically predictive of outcome, such as BM blast cell count, karyotype, degree of pretreatment, age, performance status, and availability of a related donor.[226] Those patients with many favorable prognostic factors and an HLA-matched related donor available would be the best candidates; whereas those with many poor prognostic factors and only an URD available should be offered enrollment in investigational studies or palliation.

Acute Lymphoblastic Leukemia

In contrast to treatment of the pediatric patient with ALL, only a small minority of adults with ALL are currently cured with available induction and consolidation regimens.[227,228] Results have improved modestly with more intensive postremission chemotherapy and with tailoring of protocols to specific subsets of ALL.[229] Multicenter trials have demonstrated CR rates of 75% to 89% and leukemia-free survival rates of 33% mainly due to the intensified chemotherapy regimens.[230] ALL patients have traditionally been categorized as either standard risk or high risk. High-risk factors are older age, high white cell count, CNS involvement, B-cell phenotype, T-cell phenotype, cytogenetic abnormalities such as t(4;11), t(8;14), t(1;19), 11q23 abnormalities, Ph^+, and longer time to achieve CR.[231] In view of the poor response rates and OS of adult ALL, SCT continues to be explored and refined in an effort to bridge the gap.

The questions to be answered in adult ALL are: (1) does SCT improve outcomes over chemotherapy, (2) what is the optimal timing of SCT in standard-risk and high-risk subgroups, (3) what is the value of purging in autologous SCT, (4) is ASCT superior to auto- and nontransplant modalities, (5) is related donor superior to URD, (6) what is the appropriate treatment for relapsed ALL, and (7) what is the role of targeted therapy?

SCT has been recommended in first remission for patients with risk factors for relapse, and for standard-risk patients only after relapse. The international ALL trial E2993 clearly established the favorable results of ASCT in CR1 for standard-risk patients.[232] However, the optimal treatment of postremission high-risk adult ALL has still not been clearly elucidated. The GOELAMS trial concurred that early intent-to-treat allogeneic BMT was productive of significantly better outcomes than consolidation chemotherapy followed by delayed unpurged autologous SCT (6-year OS, 75% vs 41%; 6-year DFS, 72% vs 33%). Also they determined that after autologous SCT, interferon-α maintenance did not confer any advantage with respect to relapse or survival.[233]

For relapsed or high-risk disease, Thiebaut and colleagues[234] demonstrated a DFS benefit (43% vs 31%) for patients allografted versus controls, with an even more pronounced benefit noted in the high-risk cohort (DFS, 44% vs 11%, respectively). Additionally, a subsequent study demonstrated similar outcomes in the URD versus related-donor setting and for BM versus PBSC grafts. Significantly though, improved survival was noted in B-lineage ALL versus their T-lineage ALL and that DFS for younger patients was superior.[235]

After relapse, should all patients without exception be allografted? Data from the IBMTR reported a DFS of 42% in CR2. However, beyond CR2 or in primary refractory disease, the DFS is a precipitately dismal 5% to 15%. To confirm these data, two U.S. centers evaluated the relative efficacy of allogeneic BMT in CR1 ($n = 41$), complete response (CR) ≥2 ($n = 46$), or relapse ($n = 95$) and demonstrated a significantly better 5-year DFS for the early SCT group (CR1 [43%] vs CR ≥2 (23%) vs relapsed, 9%; $P < .001$) and an overall 5-year DFS of 21%. These data underscore the contention that early ASCT improves outcomes.[236] In another study of standard-risk patients in CR1 or 1(st) relapse, DFS was similar between autologous, related, and unrelated cohorts. Again, DFS was superior for transplantation in CR1. In the Ph^+ subset, 5-year DFS was clearly superior for allogeneic versus autologous SCT (30% vs 0; $P = .04$) and was further augmented by the occurrence of limited cGVHD (53% vs 22%).[237]

For patients with high-risk or relapsed ALL lacking a related histocompatible donor, autologous and URD transplantation are available options.[238] Comparatively, both URD and auto-SCT extend survival, but URD offers better protection against leukemia relapse. To confirm this assertion, an analysis of 712 patients in CR1 revealed that URD predisposed to a higher TRM in both CR1 and CR2. Conversely, relapses were more frequent in the auto-SCT arm irrespective of CR status. Although 3-year DFSs were similar for both CR1 and CR2, an advantage in initial 6-month DFS was recorded in the URD group for younger patients, patients in CR2 with initial CR1 more than 1 year, WBC fewer than 50×10^9/L), performance status ≥90%, and in those who have undergone transplantation since 1995. Of note, more URD recipients were high risk. Further analysis revealed that ex vivo purging delayed but did not abrogate engraftment. In conclusion, improvements in allo-SCT safety and refinements in patient selection are required the better to aid treatment decision making for optimal OS.[239]

For Ph^+ ALL, the greatest improvements in DFS and OS are a consequence of in vivo purging of *BCR/ABL*$^+$ transcripts by the incorporation of imatinib mesylate into pre-/post-SCT treatment regimens. This factor becomes more important when viewed in the context of quantification of MRD by reverse transcription–polymerase chain reaction (RT-PCR) to predict pre-SCT risk of relapse and therefore necessary therapy adjustment. Second, MRD quantification is used in conjunction with chimerism studies not only to predict relapse but also to modulate the GVL effect mediated by GVHD. MRD quantification therefore more precisely defines remission, prognosis, responsiveness to therapy, and expected long-term survival.[240,241]

Chronic Myelogenous Leukemia

Allogeneic HSC transplantation is an appropriate treatment for CML, with long-term survival rates exceeding 80% in some series.[242,243] However, newly developed inhibitors of the tyrosine kinase encoded by the Philadelphia chromosome has relegated transplantation to the treatment of patients with advanced disease or the rare patient with CML not responsive to that targeted therapy. Unfortunately, the probability of long-term survival decreases for patients who undergo allogeneic transplantation more than 1 year after diagnosis and for patients with more-advanced diseases, and the effect of prior therapy with a tyrosine kinase inhibitor on the outcome of transplantation is not known. CML is highly responsive to the immunologic GVD effect, and many patients in relapse after transplantation can be salvaged by the administration of donor lymphocytes.

Limited numbers of patients with CML in chronic phase or with more-advanced disease have been treated with autologous HSC transplantation.[244] In a large, single-center study of 73 patients, the survival of patients with chronic-phase disease who underwent transplantation did not differ from that of patients treated with interferon: 58% of patients with more-advanced disease achieved a complete hematologic remission, but only 10% achieved a complete cytogenetic response, and the median survival for this group of patients was only 5 months. Of speculative interest is the collection of autologous cells after cytogenetic remission is achieved by using one of the new tyrosine kinase inhibitors for subsequent use at the time of disease relapse.[245]

Chronic Lymphocytic Leukemia

To date, the factors that have limited the implementation of HSC transplantation in CLL have been the long natural history of the disease and the advanced age of most patients at diagnosis. Although traditionally considered a disease of the elderly, up to 40% and 12% of CLL patients are younger than 60 and 50 years, respectively. These younger patients invariably will die of their disease or its complications. The understanding of the pathophysiology of CLL is rapidly advancing, and risk stratification of patients is now possible through examination for chromosome 17p and 11q deletions and detection of ZAP-70 and CD38 expression.[246]

Allogeneic transplantation is very effective in the control of CLL.[247,248] In the study from Dana-Farber Cancer Institute of 162 patients with high-risk CLL who had undergone full myeloablative SCT from 1989 through 1999, 25 patients underwent related donor T cell–depleted HSC transplantation, and 137 patients without sibling donors underwent autologous SCT.[247] The 100-day mortality was similar in both groups at 4%. OSs were also similar—58% and 55% in the allogeneic and autologous cohorts, respectively. The probability of relapse after allogeneic HSC transplantation was 68%, possibly as a result of the T-cell depletion and resultant loss of the GVD effect. The exquisite sensitivity of CLL cells to the GVD effect allows the use of reduced-intensity regimens with lower risks of regimen-related mortality in these, generally, older patients.[249,250] The Seattle program described 64 patients with advanced CLL treated with a nonmyeloablative regimen of a single fraction of TBI with or without fludarabine and either related ($n = 44$) or unrelated ($n = 20$) HSC transplantation.[249] The probability of relapse was 26%, but the probability of relapse-free survival was 52%.

The extensive infiltration of BM by malignant lymphocytes complicates autologous transplantation. Investigators from the M.D. Anderson Cancer Institute reported that 6 of 11 patients treated with autologous marrow cells (7 purged ex

vivo) surviving in remission up to 29 months after transplantation.[251] Investigators at the Dana-Farber reported a high CR rate for 137 patients who received autologous BM that had been purged with multiple monoclonal antibodies.[247] However, disease relapse and a high incidence (19%) of secondary malignancies were frequent sources of late mortality in that large series. As with autologous transplantation for CML, autologous HSC transplantation for this disease is, in general, limited to clinical research protocols and cannot be generally advocated for any group of these patients.

Myeloma

Newly diagnosed multiple myeloma (MM) has become one of the most common indications for transplantation as a result of multiple randomized studies showing improved outcomes after dose-intense therapy with autologous HSC support. In 1983, McElwain and Powles[252] used melphalan, 140 mg/m^2, without stem cell support as a salvage therapy in nine patients with refractory myeloma and noted that all patients responded to treatment, with five patients achieving complete biochemical and BM responses. Further dose escalation was precluded by the hematopoietic toxicity of this drug. After multiple phase I and II studies of high-dose melphalan therapy with autologous marrow or PBSC support confirmed the feasibility of this technique,[253–255] at least 6 phase III studies comparing dose-intense with standard-dose therapy in the autologous transplant setting were published (Table 58–5).[86,256–260] The French Myeloma Intergroup reported a large-scale randomized trial (IFM 90) that randomized 200 patients to either conventional dose VMCP/VBAP or autologous BMT with melphalan and TBI after four cycles of induction treatment.[86] The findings were strikingly in favor of the dose-intense approach with improvements in CR rates (22% vs 5%) and median probabilities of event-free (27 months vs 18 months) and OSs (60+ months vs 37 months). The Medical Research Council Myeloma VII trial of 407 patients reported similar results[256]; the French group Myelome Autogreffe (MAG) achieved results comparable to the IFM 90 trial, but no significant difference in OSs was found as a result of unexpected prolonged survivals in the chemotherapy arm.[257] The Spanish PETHEMA group did not find a statistically significant difference in EFS and OS between chemotherapy and dose-intensive therapy.[258] However, only patients who responded to conventional-dose chemotherapy were randomized, and patients in the chemotherapy arm were allowed to cross over into the dose-intensive therapy group. The MRC trial comparing dose-intense with conventional therapy deserves special consideration, in that it is the most recent of the randomized trials and was carried out in the era of more-advanced supportive care and with the availability of newer therapeutic agents.[256] It still showed a statistically significant advantage for dose intensity in terms of CR, EFS, and OS. These randomized trials, all of which showed a trend to, or significantly improved results for patients treated with dose-intense therapy, with the support of numerous phase II trials, clearly indicate that dose-intense therapy with autologous HSCT should be offered to appropriate patients as part of their initial treatment. The median EFS is remarkably constant in all these trials (25–31 months). It is more difficult to analyze OS results because OS partly depends on salvage therapy. However, median OS was significantly longer in the three studies in which differences in EFS were more marked. In all studies, procedure-related death rate was less than 5% and not greater than that observed with conventional chemotherapy. Factors associated with long-term EFS included initial transplantation within 1 year of diagnosis, absence of chromosome 11 or 13 abnormalities, and a lower β_2 microglobulin at initial diagnosis.[261] About one fourth of the patients will enjoy EFSs of ≥5 years, with few additional relapses seen after 7 years.

Tandem cycles of dose-intense therapy appear to improve further the outcomes of autologous HSC transplantation. The Arkansas transplant program described 42 patients who received two consecutive autologous PBSC transplants by using melphalan, 200 mg/m^2.[262] In patients that were capable of receiving two transplants, the CR rate increased from 24% after the first transplant to 43% after two transplants. This experience has now been extended in more than 1000 patients with overall CR rates of 40% and projected 5-year EFS and OSs of 25% and 40%, respectively.[263] The French Intergroup randomized 399 newly diagnosed myeloma patients younger than 60 years to single versus tandem transplants.[264] They found similar CR rates between the two groups (42% single transplant vs 50% tandem transplant), but superior 7-year EFSs (10% vs 20%; $P = .03$) and OSs (21% vs 42%, $P = .01$) for the tandem transplant group. For patients w ho did not achieve a very good partial response (<90% reduction in serum or urine paraprotein) after one transplant, the improvement in 7-year OS was even more dramatic (11% vs 43%; $P < .01$). These results support tandem autologous transplants for patients with a diagnosis of MM who do not show disease progression after the first transplant.

Table 58–5 **Randomized Trials Comparing Conventional Chemotherapy with High-Dose Therapy in Multiple Myeloma**

				CR Rate (%)			Median EFS (mo)			Median OS (m)		
	N	Age (yr)	Median F/U	CC	HDT	*P*	CC	HDT	*P*	CC	HDT	P
IFM 90[86]	200	<65	7 yr	5	22	<.001	18	28	.01	44	57	.03
MAG91[256]	190	55–65	56 mo	NE	NE		19	25	.05	45	42	NS

CC, conventional chemotherapy; CR, complete remission; EFS, event-free survival; HDT, high-dose therapy; OS, overall survival; NE, not evaluated; NS, difference not statistically significant; F/U, follow-up; mo, months.

The incidence of myeloma increases with increasing age, and many patients with plasma cell dyscrasias have renal impairment as a result of their disease; early studies of dose-intense therapy tended to exclude these patients. However, the favorable characteristics of melphalan permit transplant therapy to be extended to patients with renal impairment, including patients with end-stage renal failure (ESRF). Pharmacokinetic studies of melphalan show comparable clearance rates regardless of renal function.[265] The Arkansas group compared 42 patients with renal failure (including 19 requiring dialysis) with 84 patients matched for other prognostic features. Regimen-related mortality was 7% for the group with renal impairment compared with 6% for those with normal renal function. Engraftment kinetics and probabilities of EFSs and OSs were also similar. This group reported a subsequent series involving 81 patients with renal insufficiency that showed no difference in quality of stem cell collection and engraftment, even for patients on dialysis.[266] This transplant group also demonstrated the tolerability of dose-intense therapy in the older patient, reporting a slight increase in 60-day mortality for patients older than 65 years (8% vs 2%). However, median EFSs (1.5 vs 2.8 years) and OSs (3.3 vs 4.8 years) were statistically similar for the older and younger patients.[267]

The EBMTR performed a case-matched study comparing 25 patients receiving syngeneic transplants with 125 patients receiving autologous transplants and 125 patients receiving allogeneic transplants.[268] They reported a CR rate of 68%, which was not significantly different from autologous (48%) or allogeneic (58%) transplants. Median OS was better for syngeneic compared with autologous (73 vs 44 months) transplants, and the progression-free survival was significantly better (72 vs 25 months). From this study, the EBMTR recommends a syngeneic transplant if an identical twin donor is available.

Allogeneic transplantation after dose-intense therapy in the treatment of myeloma is characterized by unacceptable transplant-related morbidity, approaching 40% by day 100.[269] Use of a reduced-intensity conditioning regimen decreases the risk of regimen-related mortality to less than 20%, but patients with advanced disease are unlikely to respond to this treatment.[270] The lower risk of complications with nonmyeloablative conditioning regimens has led to studies of tandem autologous transplantation (to achieve dose-intense tumor debulking) followed by allogeneic transplantation (to achieve immunotherapy). In a study of tandem autologous followed by allogeneic transplantation published by Maloney and associates[271] the median days of neutropenia and hospitalization and the median number of platelet transfusions after allogeneic transplantation with a conditioning regimen of 2-Gy TBI were each 0. However, a similar study of patients with adverse risk features including chromosome 13 abnormalities did not demonstrate a benefit of tandem autologous followed by allogeneic transplantation in comparison to tandem cycles with autologous HSC support.[272]

The Amyloidoses

Primary amyloidosis, recognized as plasma cell dyscrasia in 1931, is a protein-conformation disorder caused by a clonal plasma cell disorder. The plasma cells in the BM produce a monoclonal immunoglobulin protein. The M protein light chains or light-chain fragments form insoluble fibrils from β-pleated sheet aggregates that are deposited into the extracellular matrix in kidney, heart, liver, gut, peripheral nervous system, and other tissues. The deposits disrupt organ function and ultimately lead to death. The two most common forms, amyloid light chain (AL) and reactive, may be primary, secondary, or familial, with 21 causative proteins identified to date. The prognosis of systemic AL amyloidosis is poor; fewer than 5% of all patients survive 10 years or longer. With conventional chemotherapy, such as vincristine, doxorubicin (Adriamycin), and dexamethasone (VAD), the median survival could be prolonged by 4 months.

In a study from MSKCC, Comenzo and colleagues[273] concluded that all patients with systemic amyloid syndromes (more than two organ systems) should be considered for PBSCT because no other modality of therapy is as effective in achieving complete hematologic responses and reversal of amyloid-related organ dysfunction in 66% of surviving patients. Autologous SCT is the treatment of choice because AL deposits in BM do not obviously impair stem cell mobilization. G-CSF mobilization is the standard recommended approach. The CD34+ optimal recommended dose is 5E+06/kg. More importantly, CD34+ selected cells require the same time to myeloid engraftment as unselected cells but have delayed lymphoid recovery with increased incidence of opportunistic infections. This procedure, however, remains controversial because TRM in AL amyloidosis is substantially higher (15%–40%) than in MM (<5%). The same study also explored the role of cytoreduction before autologous SCT. They found that reducing clonotypic cells yielded no benefit in DFS or OS in MM studies and hence questionable utility in AL.

In another study by DiSpenzieri and coworkers[274] 63 PBSCT case and 63 control subjects were strictly matched. OS at 1, 2, and 4 years from diagnosis were 89% and 71%, 81% and 55%, and 71% and 41% ($P < .001$) in favor of the SCT cohort. Additionally, the OS rates at 1, 2, and 4 years from start of therapy were 82% and 68%, 81% and 53%, and 70% and 40% ($P < .001$) for the PBSCT and conventional therapy cohorts, respectively. Randomized studies have shown that treatment with high-dose melphalan (HDM) and autologous stem cell transplantation (ASCT) of selected patients has been effective in arresting and even reversing the disease course with induction of CRs. Responders who achieve a complete disappearance of light-chain secretion are more likely to achieve reversal of underlying organ dysfunction.[275] Multiorgan disease, and cardiac dysfunction in particular, predicts poor transplant outcome. AL invariably has multisystem involvement and, indeed, one of the major criteria for post-transplant survival is intact organ function, specifically renal and cardiac function. (In one study, the EFS was 60% for patients with cardiac involvement but 100% for patients with renal involvement and no evidence of cardiac dysfunction.[278])

To this end, recent reports by Gillmore and colleagues[277] and Leung and colleagues[278] have detailed their individual successes with tandem cardiac and tandem living donor renal autologous SCT, respectively. However, genetic testing to document the presence of the *VλV1IGL6VS1* and *DPL2* mutations seen in cardiac and renal AL involvement, respectively, is still not widely used.[279]

Waldenström's Macroglobulinemia

Waldenström's macroglobulinemia (WM) is a rare monoclonal gammopathy associated with lymphoplasmacytic lymphoma.[280] It has been a hitherto incurable lymphoproliferative disorder characterized by the production of IgM

paraprotein.[281] Asymptomatic WM patients who are diagnosed by chance need not be treated, and initiation of treatment should not be based on level of serum monoclonal protein per se but rather on the presence of cytopenia, significant adenopathy or organomegaly, symptomatic hyperviscosity, severe neuropathy, or cryoglobulinemia.[282]

The need for rapid disease control may favor the use of nucleoside analogs, although it may be prudent to avoid these agents in patients who are candidates for high-dose therapy because of the deleterious effects on subsequent HSC collection.[283,284] The presence of significant cytopenias may favor rituximab.[285] Despite the lack of randomized trials, a rational approach to the treatment of patients with WM is possible. Several factors, including the presence of cytopenias and need for rapid disease control, imply candidacy for high-dose therapy with autologous HSCT, which may induce responses even in patients with resistance to all three classes of agents (Table 58–6).[286]

Desikan and associates[287] reported a study of six patients conditioned with melphalan and TBI followed by autologous stem cell rescue. Five patients achieved a PR with EFS ranging from 2 to 52 months, and one patient achieved a durable CR. In this study, the importance of restriction of excessive purine analog use to the post–stem cell–collection period was stressed. This B-cell disorder appears to be sensitive to a GVL effect, and allogeneic transplantation may be effective in the treatment of patients with WM. Martino and colleagues[288] reported on two patients who had undergone ASCT after multiple relapses and have EFSs of 3 and 9 years. More studies need to be performed to elucidate the GVL effect of the allograft.

Non-Hodgkin's Lymphoma

The lymphomas represent a diverse group of malignancies. The incidence has doubled within the past 3 decades with 55,000 to 60,000 new cases diagnosed annually in the United States. These statistics represent a 3% annual increase within this period.[289,290] These malignancies have been reclassified by the WHO into B-cell and T-cell neoplasms.[291] Increasingly an association with chronic inflammatory disorders (Sjögren syndrome), chronic infection (*Helicobacter pylori,* EBV) and immune suppression (solid organ transplant) has been noted in the pathogenesis of the NHLs.[292] As a group, the lymphomas are highly responsive to chemotherapy, radiation, radioimmunotherapy (RIT), and increasingly biologic therapies such as monoclonal antibodies (anti-CD20, rituximab; anti-CD52, alemtuzumab) and a variety of vaccine-based therapies. Importantly, prognostic indices (IPI, FLIPI) and genetic and molecular markers in combination with the histology and extent of disease are increasingly being used to aid and refine treatment decisions.[293,294] Despite these advances, the majority of patients experience some initial responses, but only a minority are cured.

These tumors exhibit a strong dose-response relation, and the benefit of high-dose treatment with autologous stem cell rescue is well established for some categories of this disease. Several high-dose chemotherapy regimens have been developed for the treatment of the lymphomas. Radiation-based regimens, including CY with TBI and etoposide plus TBI, have significant activity but frequently are difficult to administer in that many patients have already been exposed to radiotherapy. Popular chemotherapy regimens include CY, BCNU, and etoposide (CBV) and BCNU, etoposide, Ara-C, and melphelan (BEAM). However, no single chemotherapeutic regimen has emerged as a superior treatment.

Autologous HSCT is a standard of care for many patients with NHL either in the treatment of relapse or as consolidation therapy for patients with aggressive disease. The success of this therapy reflects the extent and the responsiveness of the disease to chemotherapy at the time of transplantation. Relapse is the major cause of failure of autologous transplantation.

Indolent Non-Hodgkin's Lymphoma

In low-grade NHL, conventional chemotherapy has increased PFS, but OS has not been improved. Low-grade NHL, in general, exhibits a variable and prolonged natural course, with many patients not requiring treatment until symptoms or organ toxicity appear. Therefore, most of the experience with HSC transplantation has been in patients after initial relapse rather than at initial diagnosis, avoiding the potential for the morbidity and mortality of dose-intense therapy. The optimal timing of HSC transplantation (consolidation vs salvage) remains to be determined by prospective randomized trials, such as the ongoing multicenter trial of the German Low-grade Lymphoma Study Group, which indicates that up-front transplant after CHOP/MCP (mitoxantrone, chlorambucil, and prednisone) induction produces significant prolongation of PFS versus maintenance in patients attaining CR/PR.[295]

Clearly, HSC0 transplantation aims to eradicate residual tumor cells and prolongs OS, although it certainly does not guarantee cure, with the majority of patients eventually

Table 58–6 **Autologous Stem-Cell Transplantation in Waldenström Macroglobulinemia**

Reference	No. of Patients	Median age (yr)	Disease Status	Response (%)	CR (%)
Desikan et al[287]	8	58	Relapse	100	13
Anagnostopoulos et al[286]	4	49	Refractory	75	0
Tournilhac et al[393]	18	55	Chemosensitive, $n = 14$; chemoresistant, $n = 4$	95	11
Dreger et al[392]	10	51	First response or primary refractory	100	14

CR, complete response; WM, Waldenström macroglobulinemia.

relapsing.[296] Current data suggest that noncontaminated grafting (obtained with stem cell purging) does improve OS. As an example, up-front purged autograft (TBI, etoposide, CY) has proven to be valuable in patients with advanced follicular lymphoma, providing 10-year disease-specific survival of 97% with an RR of 30%.[297] However, data from prospective randomized trials comparing purged versus unpurged autografts are pending. A number of phase II and registry data have been published. Although response rates are high, a continuing pattern of relapse has been observed with autologous transplant. Bierman and colleagues[298] reported a 68% CR rate for a single-center series of 100 patients with relapsed disease but, at a median of 4 years, a probability of failure-free survival of 44% with no plateau to the curve depicting probability of relapse. The Dana-Farber transplant program reported a series of 86 patients with advanced follicular lymphoma who underwent autologous marrow transplantation as part of initial therapy in a publication that raised the question about the necessity for and efficacy of tumor cell purging.[299] Patients who received marrow products that were free of disease (based on a sensitive PCR detection technique for the t(14;18) abnormality commonly found in follicular NHL) experienced a much lower rate of relapse than did similar patients whose products contained detectable tumor after purging. However, again, no plateau to the curve depicting probability of relapse was reported.

The indolent lymphomas exhibit a strong response to the GVL effect of allogeneic transplantation and appears to provide the best chances for cure, providing a noncontaminated graft along with a graft versus lymphoma (GVL) effect.[300,301] Reduced intensity SCT may therefore be a reasonable approach in patients with advanced disease, allowing a GVL effect with less toxicity compared with conventional allograft. However, data are still limited, and follow-up in the majority of studies is relatively short, highlighting the need for longer follow-up to establish the role of reduced-intensity SCT in low-grade lymphoma.[302] Patients who undergo allogeneic transplantation will experience a higher probability of transplant-related mortality, but a lower risk of relapse after transplantation.[303] The difference in relapse rates could result from reintroduction of lymphoma cells in the HSC product or from the lack of a GVD effect of autologous transplantation.

Small numbers of patients have undergone autologous HSC transplantation for indolent NHL after transformation to aggressive NHL.[304] A large proportion of these patients achieved durable remissions, suggesting that this is effective therapy and should be considered for older patients or for those lacking an allogeneic donor. For patients with refractory or recurrent indolent NHL, allogeneic has returned superior DFS and OS as compared with autologous SCT, although the high TRM continues to indicate that nonmyeloablative allogeneic SCT (NST) should be explored in controlled trials.[305]

Aggressive Non-Hodgkin's Lymphoma

The role of high-dose chemotherapy with stem cell rescue in patients with chemotherapy-sensitive aggressive (intermediate or high-grade) lymphomas in relapse has become well established. The PARMA trial clearly demonstrated superior 5-year EFS treatment (46% vs 12%; $P = .001$) and OS (53% vs 32%; $P = .038$) in favor of HDT/autologous SCT versus conventional dose treatment for patients in first chemosensitive relapse. They also found that no patients assigned to the conventional-dose salvage therapy could be rescued at the time of second relapse with a delayed transplant. Therefore, excessive pretransplant "debulking" therapy and/or delays in transplant timing should be avoided. This randomized trial, which confirmed the findings of previous phase II studies, conclusively demonstrated that transplantation therapy represents the treatment of choice for first-relapse chemosensitive aggressive NHL.[306]

The International Prognostic Index (IPI) identifies patients with aggressive NHL who have a high likelihood of relapse and poor OS with conventional first-line therapy.[307] The French LNH-87 trial examined the role of consolidation transplantation for patients in first CR after standard-dose treatment.[308] The initial analysis of this trial demonstrated no advantage gained by the addition of intensive consolidation. However, subsequent analysis, which included only those patients with high intermediate or high risk by the more restrictive criteria of the IPI, revealed a superior DFS for those patients undergoing high-dose transplant. Similarly, the Italian Non-Hodgkin's Lymphoma Study Group showed no benefit to high-dose therapy with stem cell rescue in patients judged to be at high risk by virtue of tumor bulk or advanced-stage disease.[309,310] However, a striking advantage in DFS was noted when the 70 patients who qualified as high-intermediate or high risk based on the IPI were analyzed. In this subgroup, transplantation yielded a superior 6-year DFS rate (87% vs 48%; $P = .008$). In total, these studies suggest that for patients with high-risk disease by virtue of the IPI, the use of autologous transplantation therapy may be beneficial as part of the overall initial therapeutic strategy.

In other circumstances, HSCT may be indicated, such as for the patient who responds slowly to initial therapy, has high-risk disease or disease resistant to initial therapy, and relapse with chemotherapy-insensitive disease.[311] The appropriate approach for patients who achieve less than a CR or who exhibit a slow response to conventional induction therapy is not yet clear. In one small trial of 69 slow responders to CHOP chemotherapy, the use of early transplant compared with five additional cycles of CHOP was not associated with an overall improvement in survival or EFS ($P < .10$).[312]

Analysis of the ABMTR data showed that among 184 patients who had never achieved a CR with conventional therapy (primarily induction failures), 44% could achieve a CR after autologous BM or PBSC transplantation. The probability of PFS at 5 years after transplantation was 31%. Variables predictive of poor outcome in the multivariate analysis were chemotherapy resistance, administration of multiple cycles of chemotherapy before transplantation, poor performance status at time of transplantation, older age, and the lack of use of consolidative radiotherapy before or after transplantation.[313]

Patients with diffuse large cell lymphoma (DLCL) in chemosensitive first relapse have a 40% to 50% chance of long-term DFS after autologous transplantation.[314] This approach may also confer a survival advantage for high-risk patients in first CR. Patients relapsing after an autograft have a particularly poor prognosis, with a median survival of less than 12 months.[315] Comparatively, an earlier EBMT analysis failed to demonstrate superiority for allogenic SCT versus auto-SCT, but an updated analysis by Peniket and colleagues[324] confirmed better outcomes for the allogeneic cohort despite a higher proportion of chemoresistance in this subgroup. Given the reasonable outcomes and limited toxicity of salvage high-dose therapy and autologous stem cell rescue in DLCL, allogeneic

transplantation should be considered only after autograft failure unless outcome is predicted to be particularly poor.

Mantle cell lymphoma is known for its unremitting clinical course when treated conventionally and has proven relatively resistant to high-dose treatment, especially when used as a salvage therapy.[316] Incorporating high-dose therapy into the initial overall treatment plan, however, may be more likely to provide durable remissions. At M.D. Anderson, the results of using an intensive induction regimen followed by autologous transplantation have been encouraging.[317] Among previously untreated patients, the EFS rate at 3 years was 72%. Despite this, relapse remains a problem after autologous SCT, and ASCT currently appears to provide more durable remissions. The role of high-dose therapy and autologous rescue remains unclear. Use early in the disease may improve OS, but little evidence indicates that the procedure is curative.[318] Given the lack of long-term DFS with autologous approaches, the role of allogeneic transplantation in newly diagnosed patients must be addressed in appropriate extended phase II studies.

Burkitt's lymphoma, Burkitt-like lymphomas, and lymphoblastic lymphomas are high-grade NHLs associated with relatively poor long-term survival rates. The role of both autologous and allogeneic transplantation in these disorders remains unclear. No convincing risk models identify clear indications for transplantation in CR1. Allogeneic transplantation should probably therefore be restricted to chemosensitive relapsed patients. The lack of a clear contributory benefit of GVL in these disorders suggests that for patients without BM involvement in whom a sibling is not available, autologous transplantation may provide a reasonable alternative to URD transplantation, particularly if the potential delay incurred by the donor search is likely to be considerable. Data from the EBMTR suggest that disease status at the time of transplant is the most important predictor of outcome in patients with high-grade disease.[319] For Burkitt's and Burkitt-like lymphoma, the 3-year actuarial OS rate was 72% for patients transplanted during first CR, compared with 37% in those with chemotherapy-sensitive relapse, and 7% in patients with disease that is unresponsive to chemotherapy. For patients with lymphoblastic lymphoma, the 6-year actuarial survival rate ranged from 63% in patients who were in first CR to 15% in those who had resistant disease. Patients in second CR had an intermediate survival rate of 31% at 6 years. These results with transplantation appear to be superior to those with conventional-dose salvage therapy.

T-cell lymphomas are less common entities, classified by the WHO into leukemic, nodal, and extranodal variants.[283] These lymphomas may first be seen with numerous unusual clinical syndromes (hemophagocytic syndrome, sinus tumors with angiocentric T-cell proliferation).[292] No well-defined management strategy exists for these disorders, and treatment is based on the disease stage and immunopathologic grade. Few comparative trials have been performed, and hence little evidence exists that any one combination regimen is superior to another. The relative chemotherapy sensitivity to common B cell–type treatment regimens is lower, corresponding to the inferior CR rates noted in these diseases. Some entities remain localized, such as the nasal T/NK cell lymphoma, requiring only CHOP-like chemotherapy followed by involved field radiotherapy (IFRT) and are generally associated with good prognosis. Conversely, visceral involvement such as hepatosplenic T-cell lymphoma, intestinal T-cell lymphomas, and the leukemic variants are aggressive with poor prognoses and are generally treated with high-dose chemotherapy and autologous stem cell rescue.[320] Currently, numerous novel targeted therapies are being explored for the treatment of the T-cell lymphomas.[321]

Autologous HSCT continues to be associated with a high risk of relapse because of the presence of MRD in the harvested, reinfused stem cells, or remaining in the patient after chemotherapy. As a result, monitoring and eradicating MRD has become a major focus of many studies in NHL. Rearrangement and gene expression of the bcl-1 and bcl-2 genes are the hallmarks of mantle-cell and follicular lymphoma, respectively, and evidence suggests that they are promising surrogate markers of MRD. Clearance of bcl-1/JH- and bcl-2/JH-positive cells after treatment is associated with a significant improvement in outcome.[322,323]

Allogenic HSCT continues to be investigated to improve outcomes. Allogenic HSCT has several potential advantages over autologous transplantation for NHL, including procurement of an uncontaminated stem-cell graft, GVL effects, and the elimination of HSC damage and consequent secondary leukemia. However, because of a 1-year TRM of 30% to 40% and complications caused by GVHD, conventional, myeloablative, allogeneic transplantation is a high-risk option for low-grade lymphoproliferative disorders.[326] Even though the ideal application of allogeneic transplantation in aggressive and high-grade lymphomas is still unclear, the high rates of CR and the lower relapse rates demonstrated in several comparisons of the two approaches make this an exciting area to pursue. Allo-SCT also induces complete remission in advanced lymphoma patients, even when the tumor had relapsed after autologous HSCT. Freytes and associates[325] investigated conventional myeloablative allogenic SCT in 114 relapsed patients after auto-SCT. They demonstrated higher rates of disease progression (52%), TRM (22%), 3-year OS and PFS (33% and 25%), respectively. Despite the foregoing, this approach is usually not curative. In conclusion, allo-SCT should be considered earlier as a therapeutic option in poor-risk patients to avoid the high nonrelapse mortality associated with extensive pretreatment.

Nonmyeloablative (NST) or reduced-intensity SCT broadens the applicability of allogeneic transplantation by lowering regimen-related mortality while capitalizing on the GVL effect.[326] For aggressive disease, NST is indicated only for patients with minimal disease burden, as the nonmyeloablative regimens lack the ability to control rapidly proliferating disease before the generation of a GVT effect, a major limiting factor with this modality.

Results for patients with truly chemotherapy-refractory disease are poor. Patients with disease that is unresponsive to chemotherapy at the time of relapse have a low (about 15%–20%) chance of achieving a long-term remission with high-dose therapy and stem cell rescue (Table 58–7).

Hodgkin's Disease

Many patients will achieve durable remissions with nontransplant chemotherapy and/or radiation therapy, and algorithms for staging and treatment of this disease are well defined. For patients who have a relapse, the prognosis with conventional salvage therapy is directly related to the duration of the initial remission. The outcome for patients whose remission lasted less than 1 year is dismal, and most experts concur that approximately 40% to 50% of patients with HD who have a relapse within 1 year will achieve durable remissions after autologous HSCT.[327,328]

For patients whose first remission lasts more than 1 year, two randomized trials comparing HDT/autologous SCT with conventional salvage treatment suggested similar overall long-term survival rates but possibly a greater DFS rate for the transplant arms.[329,330] Also, patients with refractory HD may achieve durable CRs with HDT/SCT. ABMTR and EBMTR analyses demonstrated that HDT can overcome drug resistance in HD. After autologous transplantation, the probability of 3-year PFS was 38% and 30%, with an OS rate of 50% and 34%, respectively.[331]

Previous reports from Seattle and Baltimore strongly suggested that allografting resulted in a lower relapse rate with evidence of a GVL effect in relapsed refractory HD. In two large registry-based randomized retrospective analyses published in 1996, Gajewski and colleagues[332] analyzed the results of 100 HD patients with advanced resistant disease, who had undergone matched-sibling SCT. The 3-year OS, DFS, and probability of relapse were 21%, 15%, and 65%, respectively. A lower relapse rate was noted in patients who developed GVHD but at the risk of higher TRM. The second analysis by Milipied and coworkers[333] of 45 autografted and 45 allografted case-matched patients revealed no significant difference in OS, PFS, relapse and nonrelapse mortality. The pattern of decreased relapse rate in 17 allografted patients with GVHD grade ≥2 was repeated compared with 17 matched autografted patients.

With the TRM from conventional myeloablative ASCTs approaching 60% in some reports, nonmyeloablative SCT (NST) is being actively studied as an alternative to classic SCT, although the question of whether the relatively low doses of cytotoxic drugs in the preparative regimens will suffice to debulk the tumor burden to a level at which the allografted T cells can expand and control residual tumor to permit lifelong remission still must be answered.

The EBMT collected data on 94 heavily pretreated patients who underwent NST.[334] Of these, 50% had failed a prior autograft, and 31% were deemed primary progressive or refractory to conventional salvage regimens. The majority of the patients received HLA-identical family donor grafts. Among the 80 evaluable patients, the OS patterns in 35 chemosensitive- and 23 chemoresistant-disease patients revealed that none of the chemoresistant patients were surviving at 1.4 years, whereas fully 78% of the chemosensitive cohort was alive at 4.3-year follow-up. Univariate and multivariate analyses confirmed that the only factor negatively influencing both OS and DFS was chemoresistant compared with chemosensitive disease ($P = .025$ and $P = .015$, respectively). This therefore underscores the importance of early selection of appropriate chemosensitive patients for NST. To this end, the EBMT has launched two new studies to better understand and exploit the true potential of NST.

HDT followed by tandem autoallogeneic transplants is being explored as a more effective approach in the relapsed refractory setting. As a prelude to this, Ahmed and associates[335] recently reported their experience with HDT combined with tandem auto-SCT. They reported a 32.14% long-term survival in their resistant/refractory group. Multivariate analysis identified age younger than 35 years and no B symptoms as predictors of superior outcome.

Marrow Failure States

The inherited BM failure syndromes are becoming less enigmatic as their genetic and molecular bases are further elucidated. These rare disorders may present only with tricytopenia, and interestingly enough, children and young adults may not display all the classically described physical characteristics. It is therefore imperative to make an early diagnosis, as it affects therapeutic approaches and management strategies. Currently the only option for reestablishing normal hematopoiesis in this patient population is HSCT.[336,337] T-cell depletion of BM or PBSC or use of UCB are frequently used to decrease GVHD, early post-transplant toxicity, and therefore promote promising early survival.[338]

Fanconi anemia is an autosomal recessive disease with a median survival of 30 years. This disorder should be suspected in any child, adolescent, or adult with BM failure, MDS, or early-onset epithelial malignancies. The only option for reestablishing normal hematopoiesis in otherwise normal patients with tricytopenia (ANC < 1000/mm^3; HgB, 8 g/dL; or platelet count, 40–50,000/mm^3) and a suitable HLA-matched sibling is HSCT. NST avoids the pitfalls of the exquisite chemotherapy and radiotherapy sensitivities unique to this patient population, thereby preventing fatal toxicity. It is recommended that all siblings be HLA typed and have their cord blood stored, as 5-year survival figures for sibling HSCT approach 75%. The 5-year OS for matched URD SCT is 58% at some centers.[339]

For dyskeratosis congenita, HSCT is not an optimal option, as there have been reports of multiple unexplained post-transplant morbidities with the development of fatal lung toxicities and secondary cancers. Currently HSCT is recommended only in the context of clinical trials.

In the Schwachman-Diamond syndrome, exocrine pancreatic insufficiency, and clonal evolution to MDS and AML are the consistent features of this chromosome 7 autosomal recessive disorder.[340] Hypoplastic granulopoiesis is the most reliable hematologic abnormality with more than 90% of patients demonstrating neutropenia; 40%, anemia; 28%, thrombocytopenia; but only 20% with tricytopenia.[341] However, the rarity of this disorder limits large-scale trials with no consensus recommendations. Therefore, each case is managed on an individual basis with a distinctive trend toward management by SCT after preparation with attenuated conditioning regimens.

The Diamond-Blackfan syndrome occurs with pure red cell aplasia, elevated HB F and RBC adenosine deaminase (ADA), and is also classified as a cancer-predisposition syndrome. Sibling-matched HSCT confers an actuarial survival of approximately 80, although reserved for steroid-refractory cases. As previously noted for the other BM failure states, early typing of the proband and siblings and also preservation of UCB samples are strongly advocated.

Aplastic anemia (AA) is a disorder characterized by tricytopenia with concomitant hypocellular BM. This disorder preferentially affects adolescents and individuals older than 60 years. Diverse etiologies are proposed with the current focus on an autoimmune origin. It is critical to differentiate AA from hypoplastic MDS, hairy cell leukemia (HCL), and the HCL variant because of the differing treatment strategies used. Immunosuppressive therapy (IST) is the current frontline option with a remission rate close to 70%, an 80% to 90% 5-year EFS in responding patients, and a relapse rate of 10%. For the 30% of patients who have an HLA-matched sibling donor, BM or PBSCT has yielded cure rates of approximately 90% and graft failure/rejection rates of 5% to 10%.[342] The decision-making process for selection of patients must take into account the fact that younger patients tolerate SCT

significantly better and have fewer long-term issues with GVHD than their older counterparts.[343] Even though in one retrospective study, the OS for BMT and IST were no different (63% vs 61%) for all comers, the preponderance of evidence significantly favored the choice of BMT for younger patients (64% vs 38%). As a corollary to the foregoing, because some patients may require IST for up to 6 months to achieve resolution of neutropenia, therefore even middle-aged patients with an HLA-matched sibling donor and few comorbid conditions must be seriously considered for early HSCT because the risk of mortality from infectious complications increases exponentially with the increased duration of neutropenia.

Sickle cell disease (SCD) is a single-nucleotide genetic disorder with protean manifestations contributing to relentlessly omnipresent morbidity. Currently, HSCT is the only curative modality of treatment for this disorder. The two cardinal concepts of SCT in SCD are that (1) engraftment of normal donor cells ameliorates ongoing pathologic effects, and (2) mixed chimerism was sufficient to achieve this diminution of progressive chronic organ damage. Wu and colleagues[344] reported that after SCT, ineffective native erythropoiesis of Hbss provides a growth advantage for HbA or heterozygous Hbs/HbA donor-derived erythroid precursors, resulting in improvement of clinical disease. By virtue of the nature of inheritance of the genetic mutation responsible for this disorder and other factors, significant difficulty exists in finding appropriate matched sibling donors, with only 20% having suitable donors available, therefore requiring wider employment of matched URD SCT with the attendant undesirable complication of GVHD, which typically is worse in adults.[340] Results of HSCT in 200 patients who had undergone myeloablative SCT from matched-sibling donors demonstrated an 85% DFS, 7% TRM, and 9% graft failure rate with recrudescence of the SCD genotype.[346] To combat this, and as previously stated, because at worst only a minority fraction of donor-derived stem cells was necessary to achieve mixed chimerism, NST appears to be a much more attractive modality of treatment. This principle was initially established by Krishnamurthi and others[344] and further elucidated by Chakrabarti and Beresford[347] who commented on a multicenter study in which the U.S. arm donor chimerism ranged from 11% with representative Hbs of only 7%, to 99% with all patients experiencing stable mixed chimerism and resolution of SCD symptoms.

Myeloproliferative Disorders

The myeloproliferative disorders (MPDs) are clonal stem cell diseases. Based on the WHO classification, they comprise Philadelphia (Ph) chromosome/BCR-ABL–positive CML, polycythemia vera (PV), idiopathic myelofibrosis (IF), essential thrombocytosis (ET), and, more recently, chronic myelomonocytic leukemia (CMML) and atypical CML(Ph/BCR-ABL negative).[348] These disorders display overlapping clinical features but exhibit different natural histories and different therapeutic requirements. Phenotypic mimicry among these disorders, between them and nonclonal hematopoietic disorders, lack of clonal diagnostic markers, lack of understanding of their molecular bases and paucity of controlled, prospective therapeutic trials have made the diagnosis and management of these disorders problematically difficult. A potentially curative approach is allogeneic HSCT, although limited data exist on the impact of HSCT on the natural history of these disorders.[349] The preparative regimens used in fully ablative techniques rule out older patients for consideration, and many younger patients with good prognostic criteria may do sufficiently well on medical treatment or observation to avoid transplantation.[350] Indeed, some[351] have suggested that specific inhibitory molecules analogous to imatinib may be designed for each disease or disease subtype, and future trends may be identification and exploitation of the basic mechanism underlying the GVL effect for eradication of minimal residual disease without the need for allografting. Older patients may have the option to undergo an HLA-identical sibling NST to minimize peritransplant toxicity and mortality. Thus, a prerequisite to the broad use of transplantation is objective determination of candidacy. Several evaluation methods agree that anemia, age, and cytogenetic abnormalities all predict poor survival in IF, suggesting that patients with anemia and an abnormal karyotype undergo allogenic HSCT. Ample scope remains for improving the clinical results of allogenic HSCT, which in theory should "cure" most patients with MPD. The median survival for patients with myelofibrosis ranges from 13 to 93 months and myeloablative allogeneic transplantation results in high rates of durable engraftment and cure in approximately 50% of patients.

Three studies by Mittal and associates,[349] Przepiorka and associates,[352] and Anderson and associates[353] have demonstrated the effectiveness of SCT in these disorders challenging the previously held belief that this procedure resulted in delayed hematopoietic recovery.[352,353] TRM, associated with more-advanced disease and age rather than disease recurrence, accounts for the majority of treatment failures. In the Mittal study, four of six atypical CML patients died, underscoring the worse prognosis of this disorder. More recently, reduced-intensity conditioning regimens have been shown to induce encouraging rates of engraftment and prolonged survival by exploiting the GVT effect mediated by donor immunocompetent cells.[354]

Rondelli and colleagues published their small study of 21 patients in support of the use and efficacy of NST in IF. Eighty percent of the cohort displayed grades III to IV myelofibrosis. The patients all underwent fludarabine-based conditioning. Post-transplantation chimerism analysis showed more than 95% donor cells in 18 patients. Acute GVHD, grades II to IV, was observed in 7 patients, grades III to IV in 2, and extensive chronic GVHD in 8. Eighteen patients were surviving at 12 to 122 months (median, 31 months) after transplantation with 17 in remission (1 after a second transplantation). They concluded that the use of RIC regimens in allogenic SCT results in prolonged survival in intermediate/high-risk IF patients.[355] With regard to CMML, Zang and associates[356] reported on 12 patients who had undergone myeloablative allogenic SCT. They noted that early HSCT recipients (disease duration <12 months) enjoyed better survival than did those with disease duration ≥12months.

Myelodyplasia

The myelodysplastic syndrome (MDS) comprises a heterogeneous group of hematologic disorders. They are characterized by a clonal HSC abnormality engendering variable degrees of cytopenias, lineage dysplasias, and frequent evolution to AML. Currently, HSCT is the only modality of treatment that can accomplish palliation of anemia, trilineage response, cytogenetic response, delay to transformation to AML, improve survival, and, most importantly, achieve a cure. HSCT for MDS is characterized by high TRM, especially in older patients and those with more-advanced disease and

secondary MDS. Outcomes after PBSCT may be superior to earlier results with BMT.[357,358] In a report from the NMDP by Castro-Malaspina on 510 patients treated with URD BMT, the TRM ranged from 40% to 50%. Martino and coworkers[288] reported on 43 patients (aged 12–73 years; median, 49 years) who had received an HLA-identical sibling donor PBSCT. Twenty-three patients aged 55 years or older without prohibitive comorbidity received myeloablative TBI-based conditioning, followed by a T cell–depleted PBSCT and delayed DLI. Older patients or those with comorbidities (n = 20) received reduced-intensity conditioning and an unmanipulated PBSCT. Thirty-seven (86%) had advanced disease. The median follow-up was 18 months. Actuarial probabilities of 3-year OS, DFS, relapse, and TRM were 64%, 59%, 26%, and 23%, respectively, for 34 primary MDS patients. The best results were seen in 19 patients 50 years of age or older undergoing myeloablative PBSCT. Outcomes for all stages of primary MDS were improved over the data for marrow SCT, confirming a GVL effect for RIST. However, results for therapy-related MDS remained dismal, with a high relapse rate (89%).

Nakai and colleagues[359] evaluated the impact of chemotherapy before allo-SCT. In an analysis of the data of 283 patients who underwent allo-SCT from an HLA-identical sibling donor for MDS that were reported to the Japan Society for Hematopoietic Cell Transplantation, multivariate analyses identified karyotype, FAB classification, and the history of chemotherapy before allo-SCT as significant predictors for OS. OS at 5 years was 57% for patients who underwent allo-SCT as a primary treatment for refractory anemia with excess blasts in transformation (RAEB-t) or secondary acute myeloid leukemia (AML) and 54% for those who underwent allo-SCT in remission after induction chemotherapy (P = .81). These results do not support the administration of induction chemotherapy for patients with RAEB-t or secondary AML before allo-SCT. As a corollary to the foregoing, Kebriaei and associates[360] investigated the impact of disease burden at the time of myeloablative or RIST ASCT in a cohort of 68 patients (60 AML, 8 MDS). After multivariate analysis, they concluded that the factors predicting a worse outcome were increased blast count in the BM at HSCT, presence of GVHD, mismatched donor, Zubrod performance of ≥2, age 45 years or older, and residual cytogenetic abnormalities. These data support an association between pre-SCT disease burden and quality of outcome.

Solid Tumors

Autologous transplantation for the treatment of solid tumors is less established, primarily because most malignancies do not exhibit the strong dose response to myelosuppressive chemotherapeutic agents. Exceptions to this are germ cell tumors and some pediatric malignancies, such as neuroblastoma. Breast cancer, which at one point was the most frequent indication for autologous transplantation,[134] is still a subject of controversy pending the final analysis of randomized trials. Small-cell lung cancer and ovarian carcinoma are still being studied in clinical trials of autologous transplantation.

Breast Cancer

Approximately 180,000 women in the United States will develop this cancer each year, and nearly 40,000 will die. Although disease confined to the breasts and the lymph nodes is curable with multimodality therapy including surgery, radiation, chemotherapy, and hormone manipulation, once breast cancer has spread to distant organs, cure may not be possible. Therefore, all efforts to treat patients in an aggressive fashion in hopes of preventing distant spread are typically undertaken. The use of adjuvant chemotherapy became commonplace in the treatment of patients with breast cancer involving axillary lymph nodes as a result of clinical trials showing improved EFS for patients at high risk of developing metastatic disease.

To date, 18 randomized trials of high-dose therapy in breast cancer have been published.[361] Overall the consensus has been that with stage II (or above) disease, inflammatory or metastatic breast cancer prognosis is poor. Inflammatory breast cancer represents a unique clinical entity with a high propensity for both local and distant metastatic spread. Given the rarity of inflammatory breast carcinoma, no formal randomized trials have been performed in this disease. Metastatic breast cancer rarely is curable, although some women will benefit from a more-indolent course lasting years, with responses to a variety of different regimens. A role of dose-intense therapy is not clear for this stage of this disease. Currently combinations of chemotherapy and subsequently, tamoxifen or an aromatase inhibitor, have improved survival.[362,363] Trastuzumab is an encouraging example of the exploitation of a newer mechanism of action, monoclonal antibody–based immunotherapy, to produce antitumor effects in patients with metastatic tumor.

Demonstration of the efficacy of conventional adjuvant therapy with and without auto-SCT was published by Tallman and colleagues[364] who were able to achieve superior results in the combined chemotherapy transplant arm. Studies of autologous transplant as adjuvant consolidation in high-risk breast cancer have varied in the chemotherapy regimen. Because of the historic trials detailing improved outcomes with high-dose chemotherapy in high-risk patients,[365] German investigators first studied double high-dose doxorubicin (Adriamycin), paclitaxel, CY, and thiotepa as a four-drug regimen preparatory to autologous-PBS transplantation. Of the 21 evaluable patients, 8 were able to achieve CR, and 10 achieved PR. At 3 years, 4 patients remained in CR.[366] Sayer et al.[367] then studied the feasibility of intensive tandem high-dose chemotherapy consisting of epirubicin, CY, and thiotepa versus epirubicin and cyclophosphamide followed by accelerated CY, methotrexate, and fluorouracil. They demonstrated no TRM, and the intent-to-treat analysis showed a 4-year EFS of 60% versus 40% in the control arm, with an OS of 75% versus 70% (P = .02.) These findings are in contrast to other studies but reflect a difference in the design of the chemotherapy regimens.

Although statistically significant evidence indicates that high-dose chemotherapy and auto-SCT improve EFS compared with conventional chemotherapy, no consensus exists that an OS benefit results from this approach.[367]

Full myeloablative allogeneic transplantation for breast cancer has been explored by several investigators; these studies have produced preliminary and indirect evidence for a graft-versus–breast cancer effect.[368,369] Allogeneic lymphocytes can induce regression of advanced metastatic breast cancer. These results indicate that an immunological GVT effect from allogeneic lymphocytes exists against metastatic breast cancer and provide rationale for further development of allogeneic cellular therapy.[370] Currently, reduced-intensity or nonmyeloablative regimens that have less TRM but preserve the T cell–mediated GVT effects led to increased

investigation of allo-HSCT in MBC.[371] To distinguish an immunologic GVT effect from any antitumor effect of cytotoxic chemotherapy in the transplant-conditioning regimen, allogeneic T lymphocytes were removed from the stem-cell graft and were subsequently administered late after allo-HSCT. The responses, observed in 20% to 40% of patients, appear to be associated with the development of complete donor lymphoid chimerism and may be delayed with objective tumor regressions occurring after day +28 after allo-HSCT. These results indicate that an immunologic GVT effect from allogeneic lymphocytes exists against metastatic breast cancer and provide a rationale for further development of allogeneic cellular therapy for this largely incurable disease.[372]

Germ Cell Tumors

Germ cell cancers are relatively uncommon diseases accounting for about 1% of all malignancies in (primarily, adolescent and young) men. Germ cell tumors, highly curable with nontransplant therapies, are classified as seminomatous or nonseminomatous tumors.

Despite a propensity for metastatic spread, germ cell cancers remain one of the most highly curable human malignancies. For example, more than 60% of patients with high-risk disseminated disease will achieve durable responses after treatment with four cycles of cis-platinum, etoposide, and bleomycin. Patients with refractory disease or who relapse after initial treatment can be effectively rescued with one or two cycles of dose-intense therapy.

Forty cis-platinum–refractory patients were entered into a large multi-institutional phase II (ECOG-sponsored) trial of carboplatinum and etoposide, of whom 58% (22 patients) were able to proceed to a second cycle.[373] Toxicity included five (13%) patients dying of treatment-related causes, including infection, hemorrhage, and hepatic veno-occlusive disease. All treatment-related deaths occurred during the first course of therapy. Nine (24%) patients achieved a CR (including two patients after surgical resection of residual disease). Another eight patients achieved a PR for an overall response rate of 45%. Three of the CRs occurred after the first BMT, and for four patients, the PR converted to CR after the second BMT. Five of the 9 patients were alive and free of disease at a minimum follow-up of 18 months. A striking finding of this study was the poor outcome in patients with nonseminomatous primary mediastinal germ cell tumors. Eleven patients with this diagnosis were enrolled in this study, and none obtained a durable CR.

The initial ECOG experience with multiple cycles of high-dose therapy has been replicated at single centers. The Memorial Sloan Kettering group treated 58 patients with refractory germ cell tumors with two cycles of high-dose carboplatin, etoposide, and cisplatin; 40% achieved a CR, with a 2-year survival rate of 31%. Patients having pretreatment β-human chorionic gonadotropin (HCG) values less than 100 and those without retroperitoneal masses fared better.[374]

The Indiana University group reported 25 patients who had relapsed after cis-platinum–based regimens.[375] Patients received one to two cycles of conventional-dose salvage, followed by two cycles of high-dose carboplatin and etoposide with stem cell support. At a median of 26 months of follow-up, 13 (52%) patients remain progression free. This very aggressive schedule resulted in one of the highest response rates noted to date. Based on this and other reports from this program, two cycles of dose-intense therapy with autologous transplantation is now considered to be standard for patients for whom initial therapy fails.

Ovarian Carcinoma

Autologous transplantation for the treatment of ovarian carcinoma remains under active investigation, but promising results have been reported for some groups of women.[376–378] A randomized study of high-dose chemotherapy for women with low amounts of residual tumor demonstrated a prolongation of DFS for women who received the dose-intense regimen.[375] The median survival for these women was 22 months, compared with 11 months for women who received standard-dose chemotherapy ($P = .03$). Bengala and colleagues[380] recently published the EBMT retrospective analysis on the utility of high-dose chemotherapy with autologous stem cell rescue for 91 advanced ovarian cancer patients in first remission. No subgroup of patients likely to benefit in particular from dose-intense therapy could be identified, but the median duration of remission had not been reached for patients who had no residual disease. These studies indicate that remission status at time of transplantation and the ability to achieve a CR after transplantation are determining factors for long-term responses. Preliminary studies of allogeneic transplantation demonstrate a potential GVD effect in this patient population, and studies involving allogeneic transplantation are ongoing.[381]

Renal Cell Carcinoma

Renal cell carcinoma has a response rate to most chemotherapeutic agents of only about 5%. In contrast, immunotherapy with agents such as interleukin-2 have response rates as high as 15% to 20%, justifying attempts to achieve disease control through allogeneic transplantation. Investigators at the National Institutes of Health reported a seminal trial of 45 patients who were conditioned with a reduced-intensity regimen of fludarabine and CY.[382] Twenty of the patients achieved PR and CR, with four patients experiencing complete regression of all metastatic disease. The response was delayed, at a median of 5 months, and observed only for patients who developed clinically evident GVHD. Other investigators also reported GVD effect in their cohorts despite differing preparative regimens. Others have reported similar experiences, although only a minority of patients benefit from this therapy.[383] These studies, however, demonstrate the feasibility of using the GVD effect in the treatment of solid tumors.

Autoimmune Disorders

The improved safety of autologous PBSC transplantation encourages studies of dose-intense therapy in the treatment of nonmalignant diseases, including autoimmune disorders such as multiple sclerosis, scleroderma, systemic lupus erythematosus (SLE), and refractory rheumatoid arthritis. The hypothesis of currently ongoing studies is that dose-intense lymphoablative conditioning regimens will achieve prolonged remission or cure of these diseases by destruction of the clone of cells responsible for the disease. This hypothesis is supported by reports of remission of autoimmune diseases (e.g., rheumatoid arthritis, SLE) that existed as a comorbid condition for patients undergoing autologous or allogeneic transplantation,[384,385] although this has not been a universal finding.[386] The use of intensive chemoradiotherapy with HSC rescue offers an opportunity to deliver maximally tolerated

immunosuppression. Factors that may influence the relative efficacy of this approach include the number and relative resistance to ablation of the responsible lymphoid effector populations and the nature and persistence of the relevant antigen against which the immune response is raised. Although the pathogenesis of these disorders is not fully understood and lymphoid effectors are not well defined for these diseases, evidence points to the involvement of T and B lymphocytes. High-dose therapy followed by autologous HSC transplantation may allow the immune system to "reset" with control of the autoreactive lymphocytes. As with the treatment of malignant diseases, depletion of the unwanted lymphoid cell population from the HSC inoculum (purging) may be necessary for optimal clinical outcome. These diseases, although nonmalignant, can be equally debilitating, and appropriate patient selection is necessary so that the risks (morbidity and mortality) are appropriately balanced against the benefits (possibly, lack of progression instead of reversal of damage already incurred) of this therapy.

Some preliminary data on autologous transplantation carried out specifically for the treatment of autoimmune diseases have now been reported. Fassas and coworkers[387] reported stabilization or improvement for patients undergoing autologous transplantation for multiple sclerosis. In a recent publication, Traynor and colleagues[388] reported seven patients with SLE treated with autologous PBSC transplantation. All patients had severe active SLE refractory to conventional intensive immunosuppressive therapy, and two patients had a creatinine clearance of less than 30 mL/min. Treatment involved mobilization of PBSCs with CY, 2 g/m^2, followed by filgrastim; the PBSCs were depleted of lymphocytes by enrichment of CD34+ cells. The dose-intense immunoablative regimen consisted of cyclophosphamide, 50 mg/kg × 4, and antithymocyte globulin, 90 mg/kg. At a median of 25 (range, 12–40) months, all patients were free of clinical signs of active SLE. A larger series of patients confirms these findings, but also reported considerable regimen-related mortality.[389] Similar studies have been reported in other autoimmune disorders including rheumatoid arthritis and Crohn disease.[390,391]

Chapter 59

Umbilical Cord Blood Stem Cells: Collection, Processing, and Transplantation

Hal E. Broxmeyer

INTRODUCTION

The first cord blood transplantation was performed successfully in October 1988.[1] This clinical effort was initiated based on a basic science study coordinated by the author's laboratory that suggested umbilical cord blood as a potential source of transplantable hematopoietic stem and progenitor cells.[2] The clinical study, which demonstrated hematopoietic reconstitution in a patient with Fanconi anemia by using human leukocyte antigen (HLA)-identical sibling cells, served as the first proof-of-principal for the initiating scientific study,[2] and as a precursor to the more than 6000 umbilical/placental cord blood transplants performed to the present for a wide variety of malignant and nonmalignant disorders that required a hematopoietic stem cell transplant for treatment and cure. Similarly, the author's laboratory served as the first cord blood bank that stored the cord bloods used for the first five cord blood transplants performed as well as for two of the second five done.[2–5]

Both the laboratory[2] and clinical[1] studies were the result of a multi-institutional national study in the United States,[2] which then opened up into a multi-institutional international study between investigators in the United States and in Paris, France.[1] The background leading to both efforts has been reviewed in a number of articles.[3–6] At first, the clinical cord blood transplants were limited to HLA-matched sibling donor cord bloods, with the recipients being children.[7] These encouraging results led to the use of HLA-partially matched transplants in children and then the use of unrelated cord blood transplants that were completely and then subsequently partially matched for HLA.[8–13] However, because of the limiting number of cells that one can collect from the cord blood at the birth of the baby and the need for greater numbers of cells the larger the recipient's body weight, relatively fewer cord blood transplants have been performed in adults than in children and lower-weight individuals.[11,14–17] This is changing as transplanters have become more comfortable with the use of cord blood as a source of transplantable cells and as clinical understanding and efforts have better developed.[18–24]

CORD BLOOD TRANSPLANTS IN ADULTS

Although the number of cord blood transplants in adults is still relatively low compared with that for children, these numbers are increasing.[11,14–24] The recent article by Laughlin and colleagues[19] compared results of 150 patients being transplanted with cord blood mismatched for one or two antigens, in comparison to 367 matched and 83 one-antigen-mismatched bone marrow transplants. Overall, the recipients of the cord blood transplants were younger, and they were more likely to manifest advanced leukemia than were the recipients of bone marrow transplantation. Moreover, because of the limiting numbers of cells in cord blood compared with bone marrow collections, the recipients of cord blood transplants received a lower dose of nucleated cells. For as yet unknown reasons, which may not entirely relate to the dose of nucleated cells infused, neutrophil and platelet recovery was slower with transplantation of mismatched bone marrow and cord blood, than with matched marrow transplantation. This delayed engraftment with cord blood has been noted since the first cord blood transplant[1] and may relate to the relatively immature nature of cord blood cells. Interestingly, acute graft-versus-host disease (GVHD) was more likely to occur after mismatched marrow transplantation, but chronic GVHD was more evident after cord-blood transplantation. Recipients of mismatched bone marrow or cord blood transplants were similar in treatment-related mortality, treatment failure, and overall mortality, with no differences in the rate of relapse of leukemia. Although the authors noted infections being more prevalent with cord blood, the types of infections did not differ among the three comparison groups. An article by Rocha and associates[20] in the same issue of the *New England Journal of Medicine* as that of Laughlin and colleagues[19] evaluated outcomes in 682 adults with acute leukemia. Ninety-eight were recipients of cord blood transplantation, and 584 received bone marrow. This effort was confined to those transplants performed from 1998 to 2002.[20] The cord blood transplant recipients were younger, weighed less, and had more-advanced disease than bone marrow recipients at the time of transplantation. The authors reported lower risks of grade 2 to 4 acute GVHD, but significant delays in neutrophil recovery with cord blood. However, incidence of chronic GVHD, transplant-related mortality, relapse, and leukemia-free survival were not significantly different in the two groups. Attempts to reconcile the data[25] in these two articles[19,20] pointed to several possibilities in the two studies that might explain some of the differences noted. The article by Laughlin and colleagues[19] encompassed patients given transplants over a longer period than that of Rocha and associates[20] when the relevance of nucleated cell dose and HLA matching had not yet been fully appreciated. By restricting their analysis to after 1998, Roche and associates[20] likely had better patient and cord blood unit selectivity based on identification of

potential reasons for better patient outcomes.[22] A prospective study published by the Cord Blood Transplantation (COBLT) study group, supported in part by the U.S. National Institutes of Health, reported somewhat less-favorable results for cord blood transplantation in adults.[23] The primary end point of this study[23] was survival at 6 months, with secondary end points analyzing engraftment, GVHD, relapse, and longer-term survival. Enrollment into the program required a cord blood collection that contained more than 10^7 nucleated cells per kilogram recipient body weight with equal to or greater than four HLA-A and -B (low or intermediate resolution) and -DRB1 (high resolution) matches. Patients included those with acute and chronic myelogenous leukemia and acute lymphoblastic leukemia, as well as myelodysplastic syndrome, paroxysmal nocturnal hemoglobinuria, and non-Hodgkin's lymphoma. Of these patients, 94% were considered poor-risk candidates by criteria put forth by the National Marrow Donor Program (NMDP). The overall conclusion of the COBLT study[23] was that cord blood transplantation should continue to be performed in specialized centers with a research focus on cord blood cells because of the high treatment-related mortality and slow engraftment kinetics they noted. The less-favorable results noted by the COBLT study,[23] compared with that of the results of the articles reported earlier,[19,20] may in part reflect the much greater poor-risk patients studied in the COBLT study, even though the study was open to both good- and poor-risk patients, as defined by the NMDP. A comparative analysis of the major clinical studies for cord blood transplantation for adults was reviewed by Chao.[26]

Most cord blood transplants have been performed by using myeloablative conditioning regimens for the recipients, however, some patients have undergone nonmyeloablative conditioning,[27,28] and these have also been summarized by Chao.[26]

CURRENT AND FUTURE EFFORTS TO EXTEND THE REACH OF CORD BLOOD TRANSPLANTATION TO MORE PATIENTS

Although many unanswered questions remain regarding how to best broaden the applicability of cord blood transplantation, a major effort has gone into trying to adapt cord blood for more-efficient use in adults and high-weight individuals. Limits in the numbers of cord blood cells available in the individual collections of cord blood at the births of babies are clearly a major limiting factor in successful transplantation into adults and high-weight individuals. Current clinical practice uses in the range of greater than or equal to about 2×10^7 nucleated cells per kilogram recipient body weight. Whereas this is about a log lower than that recommended for bone marrow transplantation, this is compensated for in part by the increased frequency and quality of hematopoietic stem and progenitor cells found in the cord blood compared with bone marrow.[2,29–38] However, even being able to generate equal to or greater than 2×10^7 nucleated cells per kilogram body weight from single cord blood collections to use in adults is problematic on a routine basis. Attempts to compensate for limiting numbers of nucleated cells in single cord blood collections include (1) use of multiple cord blood units for transplantation into single recipients, (2) ex vivo expansion of single cord blood units, and (3) enhanced quality of the hematopoietic stem and progenitor cells for homing to and engraftment in the appropriate microenvironment niches of recipient bone marrow.

Use of Multiple Cord Blood Units for Transplantation into Single Recipients

This mode of using multiple cord blood units for potential transplantation is not new in concept[39] but has only recently demonstrated possible efficacy.[40] Barker and coworkers[40] evaluated the safety of combining two partially HLA cord blood units for transplantation after myeloablative conditioning in 23 patients manifesting high-risk hematologic malignancy. Of the 21 evaluable patients, all engrafted at 15 to 41 days, with a median time to engraftment of 23 days. Of interest, and not yet fully understood, engraftment was seen at 21 days for 24% of the patients with both cord bloods, and with only one cord blood in the rest of the recipients. However, only one unit predominated at 100 days in all the patients. The mystery is not only why only one cord blood unit eventually predominated, but also how to predict which of 2 units will predominate. This information would be of great interest, especially in the context of a number of clinical trials evaluating an ex vivo expanded cord blood unit in combination with an unmanipulated unit. If only one unit predominates, and it is not clear which unit will "win out," combining a manipulated cord blood unit (e.g., one that is "expanded" ex vivo) with an unmanipulated cord blood unit may make it extremely difficult to interpret the results. Thus far, neither nucleated nor CD34+ cell doses nor HLA-type of the cord blood collections is predictive of predominance in the host, and CD3+ T-cell dose, which was originally suggested as a possible criterion for predominance,[40] has not been substantiated. Many centers are currently using two or more cord blood units for transplantation, although a controlled clinical trial has not yet been performed to prove definitively that the transplantation of more than one cord blood unit is any more efficacious than that of a single unit.

Ex Vivo Expansion of Single Cord Blood Units

Hematopoietic stem cells are defined by their capacity to self-renew. Being able to harness the self-renewal capacity of these stem cells ex vivo would likely open up the possibility for more-consistent use of cord blood transplantation for adults. Also, it is possible that a single collection of cord blood, if effectively expanded in the context of functional stem cells, could be used for engraftment and repopulation of the blood cell system for multiple recipients. Harnessing self-renewal capacity for production/expansion of stem cells is clear for murine stem cells. Unfortunately, it is not apparent that anyone has been able truly ex vivo to expand human hematopoietic stem cells. Without question, ex vivo expansion of hematopoietic progenitor cells is possible, but progenitors do not have the capacity to provide the long-term engraftment needed for successful transplantation. Progenitors may to some extent provide short-term engraftment, and it is possible that this may be of some value when expanded progenitors or short-term repopulating stem cells are combined with unmanipulated cord blood units that themselves do not have a high enough nucleated cell content to guarantee long-term engraftment. The expanded progenitors may allow the long-term repopulating cells in the unmanipulated cord blood unit the opportunity to "take hold" and repopulate over the long term in the recipient.

Several clinical attempts to use ex vivo expanded cells[41,42] have not provided encouraging results, although efforts in

this area are ongoing at a number of centers. Hematopoietic stem and progenitor cells are controlled by both stromal cell interactions and soluble cytokines. Although many such key players have been identified to act on hematopoietic progenitor cells,[43] far less is known about the factors influencing stem cell self-renewal and other functions of stem cells. Players implicated in stem cell proliferation and self-renewal are Notch ligands and their receptor, Notch,[44–47] Wnt3a/Frizzled,[48–51] Hox B4/PBX1,[52–58] and Bmi-1.[59–61] Whether Notch ligands effect the long-term repopulating or short-term hematopoietic stem cell is not clear,[62,63] and no clinical reports are available yet on use of Wnt3a/Frizzled, Hox B4/PBX1, and Bmi-1 manipulation for enhancement of clinical transplantation efficiency. Other intracellular factors implicated in hematopoietic stem cell function include C/EBPα,[64] Gfi-1,[65,66] Stat5,[67,68] and possibly Stat3,[69] although a role for Stat3 in hematopoietic stem cell activity is not yet clear.[68] What is clear is that self-renewal of mouse embryonic stem cells is mediated by activation of Stat3,[70] and the author's group has preliminary evidence, from using mice in which Stat3 is conditionally deleted in hematopoietic cells, that Stat3 is involved in mouse hematopoietic cell engraftment (unpublished observations). Interestingly, mouse embryonic stem cells produce a number of factors that provide functional support for themselves as well as for hematopoietic progenitor cells.[71,72] It is possible that factors produced by embryonic stem cells may have functional activity on hematopoietic stem cells. The study of both hematopoietic stem cells and embryonic stem cells could shed light on the capacity of hematopoietic stem cells for self-renewal and engrafting capability.

Stromal cell–derived factor-1 (SDF-1/CXCL12) and its receptor, CXCR4, have been implicated in a number of functions on hematopoietic stem and progenitor cells, including directed movement, as well as the survival of these cells.[43] SDF-1/CXCL12, a stromal cell–derived factor, is also produced by mouse embryonic stem cells.[71] The author's laboratory is also investigating a potential role for SDF-1/CXCL12 in hematopoietic stem cell proliferation, self-renewal, and engrafting activity. SDF-1/CXCL12 enhances the replating capacity in vitro of multipotential and macrophage progenitor cells (unpublished observations). Because replating capacity in vitro is a measure of self-renewal of these progenitors,[33,34] it is possible that SDF-1/CXCL12 may enhance the self-renewal capacity of hematopoietic stem cells.

It is probably only a matter of time before investigators uncover the factors and mechanisms of action responsible for stem cell self-renewal. When this occurs, it is likely that ex vivo expansion of stem cells will become a reality for clinical transplantation efforts. In the meantime, another option is to enhance the capacity of hematopoietic stem cells efficiently to home to their microenvironment niches in the bone marrow, and in this way, to increase the engrafting capability of these cells.

Enhanced Homing of Hematopoietic Stem Cells for More Efficacious Engraftment of Limiting Numbers of Cells

Homing of hematopoietic stem cells is a poorly understood event but is believed to involve a coordinated series of steps involving SDF-1/CXCL12, stem cell factor, lymphocyte function-associated antigen 1 (LFA-1), the integrins VLA-4 and VLA-5, CD44, metalloproteinases, and additional players.[73,74] It is believed that not all hematopoietic stem cells, when infused into recipients, reach their microenvironmental niches where these stem cells can be nourished for optimal proliferation, self-renewal, and differentiation. Thus being able to enhance homing to the appropriate niches in the bone marrow could enhance the engrafting capability of these cells. This may be of special interest for situations such as cord blood, where sometimes only limiting numbers of cells are available for transplantation.

One possible means to enhance the stem cell homing process is to increase the efficiency of the SDF-1/CXCL12-CXCR4 axis for chemotaxis/migration/homing.[73] CD26, a cell surface component, manifests dipeptidylpeptidase IV activity. This peptidase activity truncates SDF-1/CXCL12; truncated SDF-1/CXCL12 is not active as a chemotactic activity but does block the chemotactic activity of full-length CXCL12 for hematopoietic stem/progenitor cells.[75] Thus it was reasoned by us that inhibiting or deleting the CD26 expressed on hematopoietic stem and progenitor, as well as other cell types (e.g., T cells), which could enhance the chemotactic effectiveness of SDF-1/CXCL12 by blocking truncation of SDF-1/CXCL12, might enhance homing of these cells after infusion. To test this hypothesis, mouse bone marrow cells were pretreated with either Diprotin A or Val-Pyr, both inhibitors of the peptidase activity of CD26, or bone marrow cells from CD26-/- mice were used. The cells were transplanted into lethally irradiated mice congenic for CD45 in either a competitive or noncompetitive in vivo hematopoietic stem cell–engrafting assay.[76] Inhibition or deletion of CD26 on hematopoietic stem cells greatly enhanced the homing capacity of the stem cells and led to enhanced stem cell engraftment, effects most apparent when limiting numbers of stem cells were used for engraftment. Preliminary experiments suggest that Diprotin A inhibition of CD26 on CD34+ human cord blood cells enhances the engraftment of these cells in sublethally irradiated NOD/SCID mice,[77] an assay used to evaluate human hematopoietic stem cells functionally.[35–37,78] Whether inhibition of CD26 on human stem cells, or other means to enhance homing of these cells will be of clinical efficacy to increase engraftment by using limiting numbers of cells, or will enhance the time to engraftment, a problem with cord blood stem cell transplantation, remains to be determined.

CORD BLOOD BANKING

Cord blood transplantation is dependent on being able to bank the cord blood cells, which in turn requires that these cells can be cryopreserved.

Cryopreservation of Cord Blood Stem and Progenitor Cells

The first recipient of a cord blood transplant[1] is still alive and well 17 years after the transplant. He received cord blood from his HLA-matched sister that had been cryopreserved by and stored frozen for a number of months in the author's laboratory before the actual transplant.[1,3] The longest time a cord blood has been stored in cryopreserved form before actual transplantation is not clear but is likely in the time frame of at least 5 years. Theoretically, once cord blood is appropriately frozen, the cells should remain cryopreserved for at least a lifetime, assuming of course that problems did not

exist with the freezing process, the storage, and the defrosting protocol. In actual experimental terms, cord blood cells have been stored at least up to 15 years without loss of functional hematopoietic stem and progenitor cell activity.[2,29,79,80] In the most recent study from the author's laboratory to evaluate cord blood cryopreservation,[80] highly efficient recovery was noted for granulocyte-macrophage (CFU-GM), erythroid (BFU-E), and multipotential (CFU-GEMM) progenitor cells in terms of numbers and proliferative capacity of these progenitor cells in vitro after 15 years of storage. Moreover, the recovered CD34+ population of stem/progenitor cells showed more than 250-fold ex vivo expansion of progenitor cells, and the CD34+ cells isolated after defrosting of the cord blood were able to engraft sublethally irradiated NOD/SCID mice with a frequency that was equivalent to that of freshly isolated cord blood CD34+ cells. The author's laboratory, as of the date of this writing, has cord blood cells frozen for as long as 18 to 19 years and will be able to continue to evaluate the efficacy of recovery of cryopreserved cord blood stem/progenitor cells stored over the long term. However, others continue to define more-effective cryopreservation methods for cord blood stem/progenitor cells.[81]

Cord Blood Banking

In general terms, currently two types of cord blood banks are available. There are those that store cord blood for autologous or related use. These are termed "Private" banks and usually charge an upfront fee as well as a continuing maintenance fee. Once entered into a contractual agreement with the cord blood banking company, the individual that signed the contract and/or the donor of the cord blood essentially own the blood. The other type of cord blood bank is generally called a "Public Bank." Once donated to a "Public Bank," the cord blood is no longer owned by the donor or family of the donor and is available for use, for a fee, by one who is in need of a cord blood stem cell transplant. Cord blood banking has a number of benefits,[82] which include (1) rapid availability of cord blood when needed, as the blood is stored in banks and has been HLA-typed and assessed for the possibility of infectious agents; (2) no donor risk or attrition, as collection of the cord blood is essentially an easy and safe process in the hands of experienced personnel, and can theoretically be replenished from the multitude of births every day. In contrast to registries such as the National Marrow Donor Program (NMDP) for bone marrow, the cord blood is already present, whereas when the bone marrow is needed, those who signed up to donate the marrow have to be tracked down to see if they can be found and are still willing to donate the marrow, which is obtained through an invasive although relatively safe procedure; and (3) the potential for increasing the pool of donor stem cells for ethnic and racial minorities. In addition, cord blood use opens up the probability for a lower risk of transmitting infectious diseases and appears to manifest a reduced risk of GVHD, as mismatched cord blood appears to elicit less GVHD than does mismatched bone marrow. The first operational "Public" cord blood banks were established in 1993 in New York, Milan, and Dusseldorf.[82] In 2001, a number of selected organizations were available to ensure quality and standards in cord blood banking,[82] and these included in alphabetical order: American Association of Blood Banks, American Red Cross, Bone Marrow Donors World, Cord Blood Transplantation Study, European Blood and Marrow Transplant Group (EBMT), Eurocord, Foundation for the Accreditation of Hematopoietic Cell Therapy, Group for the Collection and Expansion of Hematopoietic Cells, International Society for Hemototherapy and Graft Engineering (ISHAGE), Joint Accreditation Committee of ISHAGE-Europe and EBMT, Netcord, and National Marrow Donor Program. Many of these organizations are still available today.

Techniques have been developed and continue to be refined efficiently and safely to select donors and to collect, store, process, and distribute cord blood units to areas of need throughout the world.[82]

A recent review on new trends in umbilical cord blood transplantation,[83] cited a 2003 reference that listed about 150,000 available cord bloods from 35 different cord blood banks in 21 countries, almost all of which were typed for HLA-A, -B, and -DR, with 76% of the units typed by molecular analysis for major histocompatibility complex (MHC) class II antigens, and 49% molecularly typed for MHC class I antigens. These numbers of stored cord blood are now likely an underestimate of those cord blood units available. It was noted that most Cord Blood Banks in the United States operate under an Investigational New Drug (IND) application from the Food and Drug Administration (FDA), as well as an Institutional Review Board (IRB)-approved research consent.[83] Efforts are also still needed to define the best application of cord blood transplantation in the transplant donor-choice algorithm,[83] which currently involves a decision between use of mobilized peripheral blood, bone marrow, and cord blood as sources of transplantable and long-term engrafting stem cells.

Report from the Institute of Medicine of the National Academies of Science, U.S.A.

It was noted that the increase in numbers of cord blood banks in the United States raised a number of important questions,[84] including adequacy of cord blood inventories, standardization of collecting cord bloods, as well as their processing, storage, documentation, and quality control. Moreover, the lack of a single outcomes database has been thought to block the ability of the scientific community to determine best-practice guidelines. Because of these concerns, the U.S. Congress provided money, under a 2004 appropriations bill of the U.S. Department of Health and Human Services, to establish a U.S. National Cord Blood Bank Program under the leadership of the Health Resources and Services Administration.

The Institute of Medicine report was broken down into questions and recommendations.[84] Among the questions considered, the most specific were (1) What is the role of cord blood in hematopoietic progenitor cell (Author's note: this should have read hematopoietic stem cell) transplantation in the context of other sources of progenitor cells? (2)What is the current status of cord blood banks? (3) What is the optimal structure for the cord blood program? (4) What is the current use and utility of cord blood collections for stem cell transplants? (5) What standards should be set for storage, collection, information sharing, distribution, and outcome measures? (6) What is the best way to make cord blood units available for research? (7) What consent procedures are needed for both the research and transplantation use of cord blood? and (8) Should the cord blood program set practice guidelines for both "Public" and "Private" banks? It was recommended that a national program should

have as its primary mission the goal of maximizing access to high-quality cord blood units for patient care and research in the most efficient, cost-effective, and ethical manner.[84] This program needed to avoid duplication of efforts in services provided and the steps necessary for a transplant center to access appropriate sources of grafts, with promotion of the best possible chance for patient recovery through the establishment of high-quality, HLA-diverse cord blood units, and an integral part of the program should be support and education for all individuals involved. It was emphasized that a barrier to the goal of unimpeded access to treatment was the lack of sufficient ethnic and racial diversity in existing stored cord blood units.

Specific recommendations for banks and banking included[84] (1) identify a cord blood accrediting organization; (2) establish uniform standards for cord blood collection; (3) establish uniform quality-assurance systems; (4) establish FDA licensure of cord blood units; and (5) apply quality standards to all banks.

Specific recommendations for ethical and legal issues included[84] (1) cord blood centers need policies regarding who must provide consent; (2) informed consent should be obtained before the labor and delivery; (3) donors must be provided with clear information about their options (Author's note: This of course is not possible for cord blood donors but would likely fall up front to the parents of the baby); (4) promote the security of medical information; (5) cord blood donors must understand the limits of their rights (Author's note: Again, this is not possible for the baby).

The key functions of a National Cord Blood Program were[84] governance, database, unit selections, source of transplanted material, finances, cord blood bank selection, standards, and outcomes data.

Although the Institute of Medicine report[84] is clearly a step in the right direction, it may be some time before the differing groups in cord blood banking come to any consensus and the recommendations of the report are implemented.

CORD BLOOD CHARACTERISTICS

Cord blood contains, among a number of cell types, hematopoietic stem and progenitor cells, which are very rare in the total population; and more mature blood cells including B and T lymphocytes, natural killer cells, dendritic cells, monocytes, and granulocytes. It also contains endothelial progenitor cells and mesenchymal stem cells, the latter giving rise to a number of different cell types other than blood cells. Recent reviews are available on cord blood immune cells.[85–88] This chapter covers hematopoietic stem and progenitor cells, endothelial progenitor cells, and mesenchymal stem cells. Table 59–1 lists a brief description of these cells, but this table is not meant to be an all-encompassing assessment of knowledge about these cells. Information on many of these cells, especially those that are not hematopoietic stem and progenitor cells, is still lacking but we hope will emerge soon. Because the author is not clear how these different cells, other than those of hematopoietic stem and progenitor cells, relate to each other in terms of ontogeny and parent-progeny relations, no effort has been made to describe the ontogeny and relations of these apparently different cells to each other.

Hematopoietic Stem and Progenitor Cells

In this group of cells, most is known about hematopoietic progenitor cells in terms of their frequency and proliferative characteristics. Overall, these cells in cord blood appear to have a high quality in terms of their capacity to give rise to progeny and replate in vitro.[2,29–34] These cells are found in the CD34+ and mainly in the subset of CD34+ CD38+ cells. They can be highly enriched in the CD34+++ population, those CD34+ cells expressing the highest-density distribution of cell surface CD34 antigens. Given the right separation procedure, functional hematopoietic progenitors, as determined by in vitro colony assessment in the presence of combinations of colony-stimulating factors (CSF), such as granulocyte-macrophage CSF, interleukin-3, and erythropoietin, and potent costimulating factors such as stem cell factor and Flt3-ligand, can be found at a frequency of up to 80% in the CD34+++ preparations of sorted cells. Hematopoietic stem cells are functionally assessed by their capacity to repopulate the bone marrow of sublethally irradiated NOD/SCID mice[35–37,78] and are highly enriched in the CD34+ CD38− population of cells, but only 1 in about 700 CD34+CD38− cord blood cells is a NOD/SC1D repopulating cell (SRC). This frequency is much greater than that for SRC in bone marrow or mobilized peripheral blood.

Genomic[89–93] and proteomic[94] profiling of hematopoietic stem and progenitor cells has been reported, and future studies could shed light on profiles of stem cells and progenitor cells. However, current genomic and proteomic analysis of hematopoietic stem and progenitor cells is only as good as the methods used and the cell populations analyzed. As noted earlier, even phenotypically isolated human cord blood hematopoietic progenitor cell populations are not pure, and the best separations for human cord blood SRC only yield a preparation in which the hematopoietic stem cell population is present in rare frequency. Thus information obtained on the genomics and proteomics of human hematopoietic stem and progenitor cells has to be interpreted with caution.

Endothelial Progenitor Cells

Progenitors for endothelial cells are present in human cord blood,[95–105] and an hierarchy of cells within the endothelial progenitor cell population has been identified,[103] based on their clonogenicity and proliferative potential. The high-proliferative-potential endothelial progenitor cell achieved at least 100 population doublings and could be replated to form colonies in secondary and tertiary dishes with maintenance of high telomerase activity. Of interest, endothelial progenitor cells from cord blood had much greater proliferative potential than those found in adults.[103]

Cells with Differentiating Capacity for More than Blood Cells

Stem cells in various organs do not always meet the same definition rigor. This was especially apparent in recent discussions on the topic.[106,107] The most rigorous definition of stem cells is that for hematopoietic stem cells, which should serve as the paradigm for stem cells of all organs, but agreement on this is far from unanimous.[106]

Mesenchymal stem cells are reported to produce bone, fat, and cartilage, and this multipotentiality may be the best reason for considering a mesenchmyal stem cell to be a stem

Table 59–1 **Description of Progeny of Stem and Progenitor Cells Identified in Human Cord Blood***

Cell (Abbreviations)	Progeny	Functional Identification	Cell Surface Phenotype	Engrafting Capability in vivo	Proven Therapeutically Useful in Humans	Selected References
Hematopoietic Stem Cell (HPC)	All blood cell lineages including erythroid cells, granulocytes, monocytes/ macrophages, platelets, lymphocytes, natural killer cells (NK), dendritic cells, etc.	Repopulates bone marrow of sublethally irradiated NOD/SCID mice and bone marrow and blood of myeloablated human recipients	CD34+ CD38– CD45+ lineage–. HSC are rare within this phenotype. About 1 SCID repopulating cells is present in 700 CD34+ CD38– cells.	Yes	Yes	13, 35–38, 78
Hematopoietic Progenitor Cells (HPC):		Form colonies in vitro stimulated by cytokines. The cytokines used to stimulate colony formation determine the progenitor detected.	CD34+ CD38+ CD45+ lineage–	Yes	Not clear	2, 29–34, 38,
(i) Multipotential (CFU-GEMM: Colony Forming Unit—erythroid, granulocyte, macrophage, megakaryocyte; also termed (CFU-MIX)	Erythroid cells, granulocytes, macrophages, and megakaryocytes					
(ii) Erythroid (BFU-E: Burst Forming Unit—erythroid)	Erythroid cells					
(iii) Granulocyte Macrophage (CFU-GM) Colony-Forming unit—granulocyte, macrophage	Granulocytes, macrophages					
(iv) Granulocyte (CFU-G)	Granulocytes					
(v) Macrophage (CFU-M)	Macrophages					
(vi) Megakaryocyte (CFU-MK)	Megakaryocyte					
(vii) Lymphoid	T-lymphocyte, B-lymphocyte, NK, etc.	In vitro analysis	?	Yes	Not clear	
Endothelial Progenitor Cells (EPC)	Endothelial Cells	In vitro analysis	?	Not clear	Not clear	95–105
Mesenchymal Stem Cells (MSC)	Bone, fat, cartilage	In vitro analysis; stemness not proven and until it is proven these cells may more accurately be termed progenitor cells	CD45–; poorly characterized which leaves open the possibility that the varying differentiation capacities attributed to these cells may not be due to a single cell	Yes	Not clear	108–118
Unrestricted somatic stem cell (USSC)	Osteoblasts, chondroblasts, adipocytes, hematopoietic cells, neural cells (including astrocytes and neurons)	In vitro analysis mainly; this cell type and its differentiation capacity requires verification by other groups.	CD45–, MHC class II–	Yes (?)	Not clear	126

*Multipotential Adult Progenitor Cells (MAPC)[120–124] are not listed above as they have not yet been identified in cord blood.[125] This cell type and its differentiation capabilities still remain to be verified by other investigators.

cell. However, in most cases, these cells are poorly defined by both phenotypic markers and functional activity as actually being stem cells, at least as assessed by single isolated cells giving rise to all different tissue types.[108] Lack of evidence exists for self-renewal capacity, although their proliferative potential is not in question.

Mesenchymal stem cells are found in a number of tissues, including cord blood.[108–115] However, not all reports have shown these cells to be present in cord blood, and great variability is found in detection of the frequency of these cells in different cord blood collections, even when they are found.[116–118] This could be a technical problem of detection or may truly reflect variability in presence of mesenchymal stem cells in cord blood. Such variability and their low frequency in some cord bloods may dampen the potential therapeutic usefulness of these cells, making it difficult to translate the use of these cells into clinical application. Cryopreservation of mesenchymal stem cells has been reported.[119]

Multipotent adult progenitor cells (MAPCs), which are reported to differentiate into endothelial, epithelial, and mesenchymal cells, have been detected in bone marrow,[120–124] but not in cord blood.[125] However, an unrestricted somatic stem cell (USSC) population has been reported to be present in cord blood.[126] USSCs are CD45− and MHC class II antigen− cells, which are found in only 40% of cord blood collections (94 of 233) analyzed, and even when found, are extremely rare. In contrast to mesenchymal stem cells, the USSCs were purported to be able to differentiate into osteoblasts, chondroblasts, adipocytes, and hematopoietic and neural cells, including astrocytes and neurons.[126] They were reported to differentiate along mesodermal and endodermal pathways in vivo.[126] More information on USSCs will need to be forthcoming from the group that published the original article on this cell,[126] as well as verification from the other groups, before the true value and ramifications of its clinical relevance are appreciated.

Plasticity of stem cells, the ability of one cell to give rise to numerous cells of different tissues, is still a controversial issue, in no small part due to the lack of rigor described for the experiments performed. Moreover, other potential possibilities exist for the purported plasticity, including cell fusions and the presence of separate progenitor cells in the population, rather than one stem cell population giving rise to the different tissue types. Recent reviews and original scientific papers have discussed the issue of plasticity.[127–129] Because of the ill-defined surface characteristics of mesenchymal stem cells, it is also unclear how multipotential these cells are, and if indeed attributes associated with these cells are actually due to one cell or to a number of different cells in the population.

CONCLUDING REMARKS

Ongoing studies will delineate which cell in cord blood has what functional property and differentiation capacity and should allow us to determine whether cord blood cells can be used in cellular therapy and regenerative medicine for more than replenishment and correction of the blood cell system. It is clear that more rigorous information on the properties of the cells present in cord blood will help not only to define their ontogeny, but also further to broaden therapeutic applications of these cells.

Chapter 60

Collection and Processing of Peripheral Blood Stem Cells and Bone Marrow

Scott D. Rowley • Howard Benn

INTRODUCTION

Hematopoietic stem cell (HSC) transplantation, by definition, requires the collection and processing of HSCs from the bone marrow or peripheral circulation of the patient or a volunteer donor. Most bone marrow products are collected from the posterior iliac crests by using the techniques originally described more than 30 years ago by Thomas and Storb.[1] Bone marrow HSCs can be collected for autologous transplantation from almost all patients who are eligible for dose-intense therapy, and bone marrow harvesting from healthy donors presents little risk of serious morbidity, permitting the ethical recruitment of allogeneic donors including unrelated and pediatric bone marrow donors.[2,3] The advent of cytokine mobilization simplified the use of this cell source for transplantation. The presence of HSCs in the peripheral circulation was suggested by animal studies as early as 1951.[4] Although the nature of the survival agent was not recognized at that time, parabiosis experiments demonstrated that a factor in the blood of a healthy animal was able to rescue another animal from the effects of lethal irradiation. Subsequently, the presence of HSCs in the peripheral blood and the use of these cells to rescue animals from the marrow-lethal effects of radiation were demonstrated in a number of animal models.[5,6] Peripheral blood stem cells (PBSCs) now have virtually replaced bone marrow as the HSC component for autologous transplantation and are widely used for allogeneic transplantation. The clinical advantages and disadvantages of each cell source are described in Chapter 57.

COLLECTION OF BONE MARROW

Bone Marrow–Collection Techniques

Bone marrow is typically harvested from the posterior iliac crests.[1] Multiple aspirations are performed, with collection of about 5 mL of marrow from each puncture site to avoid dilution of the marrow sample with blood. If properly spaced, no more than two to three skin-puncture sites per side are usually required. Other harvest sites, such as the anterior iliac crests or sternum, may be used, but at increased risk of complications from accidental laceration or perforation of contiguous anatomic structures. Extending the harvest to the anterior crests or sternum is more likely to be done in patients with poor marrow function as a result of prior treatments, but is unusual, required for less than 10% of patients undergoing autologous collections.[7] For patients with a history of radiation or tumor involvement of one pelvic crest, adequate cells can be harvested from the anterior and posterior crests of the other side.

Marrow is collected in the day-surgery suite by using either general or regional anesthesia.[7] With proper fluid and blood replacement, overnight hospitalization should not be required. For the healthy donor, the risks of serious complications of either general or regional anesthesia are about the same, and choice of anesthesia can be left to the donor. Spinal or epidural anesthesia avoids the nausea that may occur with general anesthesia, especially for younger women, but hypotension from loss of vascular tone in the lower extremities often occurs as the volume of marrow is collected. General anesthesia is preferable for the donor with comorbid disorders such as cardiovascular or cerebral vascular disease because of the better control of donor airway and lower risk of hypotension. Local anesthesia is acceptable only if a limited harvest is being performed; large quantities of lidocaine used for local anesthesia are cardiotoxic, and local anesthesia does not achieve anesthesia of the interior marrow space. The operating theater is an intensive care unit, which is preferable to blood stem cell harvesting in an outpatient apheresis unit for the patient with serious comorbid illnesses.

Evaluation of Bone Marrow Donors

Anesthesia and blood loss present the greatest risks of serious complications, and patients and donors must undergo a thorough medical examination. Most marrow harvesting is performed under general anesthesia, which requires intubation for control of the airway for this surgical procedure that is performed on a prone patient. Regional (spinal or epidural) anesthesia may not be effective, so patients and donors who express a preference for this form of anesthesia must also be counseled about the potential need for general anesthesia. The health assessment must include questioning about a history of joint disease of the cervical spine and mandible and examination of the mouth if general anesthesia requiring intubation is chosen. Arthritis of the cervical spine and poor dentition may greatly increase the risk of intubation. Patients and donors with comorbid conditions such as aortic stenosis sensitive to changes in blood volume and blood pressure may require anesthesia consultation and plans for invasive monitoring during the surgical procedure. A history of marrow fibrosis, previous pelvic irradiation, or pelvic tumor involvement may exclude a patient from marrow harvesting.

All allogeneic donors must be evaluated by using the criteria currently applied to blood donors, including a targeted

history regarding behaviors exposing the donor to virus infection, recent and concurrent illnesses, and medication use.[8–11] Some groups advocate age-specific screening, possibly including marrow examination, because of the higher risk of malignant diseases in older donors.[12,13] Donors with concurrent acute illnesses should be delayed, if at all possible, because of the risk of virus transmission such as West Nile virus.[14] Numerous infectious diseases that would not exclude the donor from blood donation, such as cytomegalovirus (CMV), may be transmitted with the allograft.[15] However, donors who would otherwise be excluded for health reasons from donating blood for transfusion (e.g., history of hepatitis) may still be eligible to donate bone marrow if the needs of the recipient outweigh the risks of disease transmission. Guidance regarding the management of patients and donors with hepatitis virus infection has been published.[16] Hematopoietic disorders, such as hemoglobinopathies, will be transmitted to the recipient. Cancer can be transmitted, as illustrated by the transmission of donor leukemia not detected during initial evaluation of the donor,[17] and donors with a history of malignancy, even if in a current complete remission, should not be used if an alternate source of HSCs is available.

Complications of Bone Marrow Collection

Anesthesia complications present the major health risk to the donor or patient undergoing bone marrow collection. The actual marrow aspirations are generally well tolerated. Major complications occur in about 0.27% of healthy allogeneic donors[18] and up to 0.97% of autograft patients.[19] Complications include hemorrhage and infections at the skin-puncture sites. Severe hematomas and neuralgias rarely occur, but accidental perforation of both sides of the bone may occur, with risk of damage to vessels and nerves lying under or adjacent to the iliac crest harvest sites. Irritation of the sacral nerves, possibly requiring several months of physical therapy, may result from needle penetration through the pelvic bone into the sacral plexus or from blood tracking into the regions of the nerve roots. All donors and patients will experience localized pain at the harvest sites, which may last for several days, and may require a brief period of opioid medications.[20] Topical application of ice after collection of bone marrow may help alleviate these symptoms, and donors should be counseled to avoid strenuous exercise until after the pain has resolved. In a survey of almost 500 donors for unrelated marrow transplantation, the average time for recovery (resolution of all symptoms) was 15.8 days, although 10% of the donors required more than 30 days for complete recovery.[2] Most donors are able to return to routine activities 1 or 2 days after harvesting.

The usual volume harvested from healthy donors is about 10 to 15 mL of marrow per kilogram of recipient body weight, resulting in an average blood loss of 800 to 1000 mL. The quantity of marrow harvested from autologous patients may be greater, reflecting the previous chemotherapy given to these patients. Most donors receive blood transfusions to alleviate symptoms of volume depletion and to lessen the probability that overnight hospitalization for control of hypotension will be required. With proper preharvest autologous blood storage, the use of homologous blood for allogeneic donors should be extremely rare. For blood loss of less than 10 mL/kg, crystalloid (salt) solutions are acceptable replacement. Colloid solutions such as hydroxyethylstarch may also be used to avoid homologous blood transfusion. Blood transfusions for both autologous patients and healthy donors must be irradiated to prevent transfusion-associated graft-versus-host disease in the recipient. Donors undergoing a second harvest shortly after the first are more likely to require homologous blood.[21] Oral iron supplements should be considered for healthy donors.

Quantity of Bone Marrow Cells Harvested

Cell dose is a surrogate for the stem cell content of the marrow product. For autologous transplantation, cell doses of 1×10^8 nucleated cells/kg are adequate. Most centers target 3×10^8 nucleated cells/kg of recipient weight for allogeneic transplantation, based on early reports that smaller quantities increased the risk of engraftment failure.[22] Those reports, however, were of patients being treated for aplastic anemia, in which engraftment failure is a more common event. A study of 100 patients who received allogeneic transplantation for the treatment of acute leukemia found that cell dose per kilogram of recipient body weight (over the range of 0.5 to 13.0×10^8) did not predict the likelihood of successful engraftment.[23] A review of unrelated donor transplantation found that recipients of higher cell doses experienced faster neutrophil and platelet engraftment as well as better leukemia-free survival.[24] The pretreatment of the marrow donor with either sargramostim (GM-CSF) or filgrastim (G-CSF) may increase the number of myeloid progenitor cells harvested, especially more mature committed progenitor cells, and decrease the period of post-transplant aplasia.[25–27]

Postcollection Processing

Bone marrow is packaged in blood-transfer packs, usually after filtration to remove fat, blood clots, and bone spicules. Commercial collection kits with disposable filters are available and simplify the process of product packaging. Additional bone marrow–processing procedures including frozen or nonfrozen storage, removal or enrichment of various cell populations, and transportation are discussed later and apply to both marrow and PBSC sources.

COLLECTION OF PERIPHERAL BLOOD STEM CELLS

The ease of collection and the rapid engraftment kinetics of PBSCs compared with bone marrow, leading to shorter hospital stays and reduced costs of (autologous) transplantation, are widely recognized (Table 60–1).[28–31] Median times to achieve an absolute neutrophil count (ANC) greater than 500 per microliter are typically about 11 to 14 days, and platelet recovery is even faster.[32–37] Although graft-versus-host disease (GVHD) prophylaxis with methotrexate will slow engraftment, the kinetics of engraftment for the allogeneic PBSC recipient is similar to that experienced by the autologous PBSC recipient.[38–44] The more-rapid engraftment kinetics for recipients of PBSCs have been confirmed in a number of phase III studies involving either autologous or allogeneic HSC transplantation.[45–50] This effect is not limited to HSCs collected from the peripheral blood because cytokine administration to the patient or donor before marrow harvesting will also increase the number of HSCs collected and result in quicker hematologic recov-

Table 60–1 **Engraftment Outcomes and Costs of Transplantation for Autologous Marrow or PBSC Transplantation**

		Time to Engraftment			
Study	Patient Number	ANC >500/μL	Platelet >20,000/μL	Hospital Stay (days)	Costs
Hartmann[28]	BM 65	12	36.5*	31	$28,429
	PBSC 64	8	17.5	24	$23,591
Smith[29]	BM 31	14	23	23	$59,314
	PBSC 27	11	16	17	$45,792
Vellenga[30]	BM 42	26	18	34	$17,668
	PBSC 76	15	13	27	$13,954
Van Agthoven[31]	BM 29	15	18	34	$ 39,610
	PBSC 62	10	13	27	$ 38,742

* Platelet ≥ 50,000/μL.
BM, bone marrow; PBSC, peripheral blood stem cell.

ery.[51–55] The disadvantages to the use of PBSC components are the usual need for multiple days of collection (especially for autologous donors with poor marrow function), the current need for sophisticated flow-cytometric analysis of the components to ensure adequacy of HSC content, the inability to collect adequate components from all patients and donors, the risks associated with administration of hematopoietic cytokines and the apheresis procedures, and a possibly higher risk of GVHD, or the occurrence of GVHD that is more difficult to control.[56–58] The clinical uses of bone marrow and PBSCs are discussed in Chapter 58.

The concentration of HSCs in the peripheral blood is normally very low. Thus, very large quantities of blood must be processed to collect a quantity of HSCs equivalent to what could be collected in a single bone marrow harvest. For this reason, PBSC transplantation was limited initially to a few centers that explored this source of HSCs for patients who were otherwise ineligible for marrow harvesting. The availability of cytokines (and chemokines) with the effective mobilization of HSCs into the peripheral blood is the direct reason for the rapid and widespread adoption of PBSCs as a source of HSCs for transplantation.

Peripheral Blood Stem Cell Collection Techniques

A variety of mobilization schemes have been developed for both patients and donors. Before the availability of hematopoietic cytokines, it was noted that marrow hypoplasia–producing chemotherapy, such as that used as induction therapy for acute leukemia or the salvage therapy for non-Hodgkin's lymphoma, results in a transient increase in the number of HSCs circulating in the peripheral blood.[59–61] It was subsequently discovered that the administration of GM-CSF or G-CSF during the recovery from chemotherapy increased the numbers of circulating progenitor cells, leading to the exploration of efficacious mobilization regimens using hematopoietic cytokines, cytokine combinations, chemotherapy plus cytokines, or chemokines alone or in combination with cytokines.

Cytokine Mobilization with Granulocyte–Colony-Stimulating Factor

At present, G-CSF is the cytokine most commonly used because of its higher efficacy compared with other cytokines and its relatively benign toxicity profile. r-metHuG-CSF (filgrastim) and rHuG-CSF (lenograstim) are the two forms of this cytokine available for clinical use.[62] Slight, if any, difference between these two cytokines is found in the ability to mobilize PBSCs. Watts and colleagues[63] studied 20 healthy volunteers and found that the peak levels of colony-forming units–granulocyte macrophage (CFU-GM) in the peripheral blood were 28% higher after treatment with the glycosylated molecule (lenograstim). Hoglund and colleagues[64] found a similar comparative effect in 32 healthy male donors with an average of 104 versus 82 CD34– cells per microliter of blood ($p < .0010$) on the fifth day of administration of either drug at a dose of 10 μg/kg/day. The glycosylated molecule has a higher specific activity that may account for this difference, although some authors also suggest a gender specificity for this difference.[65] De Arriba and associates[66] treated 30 women with breast cancer in a randomized study of these two drugs by using dosages containing bioequivalent units of activity and found no difference in the mobilization of CD34+ cells. The two forms have otherwise similar biologic activity and are not further distinguished in this discussion. A pegylated form of filgrastim is now available, avoiding the need for daily injections, and may also be effective in the mobilization of PBSCs, as demonstrated in a study involving healthy donors given a single injection of 12 mg.[67]

G-CSF is the most potent cytokine currently available for the mobilization of HSCs. In a randomized study of healthy volunteers comparing G-CSF, GM-CSF, and the combination of both, Lane and colleagues[68] reported an average 0.99% CD34+ cells in the peripheral blood of healthy donors treated with 10 μg/kg/day of G-CSF compared with 0.25% for donors treated with the same dose of GM-CSF. The quantity of CD34+ cells in the peripheral blood before treatment averaged 1.6 per microliter. After GM-CSF treatment, this increased to 3 per microliter, but with G-CSF, the level increased to 61 per microliter. Each group underwent one leukapheresis on the fifth day of treatment, and the collections from donors treated with G-CSF averaged 119×10^6 CD34+ cells compared with 12.6×10^6 for the GM-CSF–treated donors. Similar results are seen in autologous transplant candidates given either cytokine after mobilization chemotherapy.[69]

A distinct time course of appearance of CD34+ cells occurs during the administration of G-CSF, with the maximal level of CD34+ cells occurring on day 5 after 4 days of G-CSF administration.[70,71] Smaller numbers of CD34+ are present on days 4 and 6, and the level decreases rapidly on subsequent days, despite a continual increase in white blood cells (WBCs).

The number of CD34+ cells collected after G-CSF treatment is proportional to the number of these cells in the peripheral blood before the initiation of this cytokine.[43] Although doses as low as 5 μg/kg/day have been used for allogeneic PBSC transplantation,[72] a dose response to G-CSF occurs, with higher average levels of CD34+ cells being achieved with 10 μg/kg/day compared with 5 μg/kg/day.[73] The average collection from one group of healthy donors treated with 10 μg/kg/day averaged 4×10^8 CD34+ cells.[73] With this dose of G-CSF and appropriate apheresis technique, adequate numbers of CD34+ cells can be collected in one procedure for transplantation of most patients. A similar dose response is observed in autologous patients and may extend to doses as high as 40 μg/kg/day.[74] Waller and colleagues[75] studied twice-daily administration of G-CSF to healthy donors and found greater yields of CD34+ cells in the apheresis component. However, the total amount of G-CSF administered was also doubled, so it is not clear if the twice-daily administration or the higher dose is responsible for this observation. Anderlini and associates[76] compared administration of 6 μg/kg given twice daily with 12 μg/kg given once daily and found no differences in CD34+ cells/L of blood processed or the yield of CD34+ cells/kg collected. A similar study, however, found a benefit to twice-daily dosing,[77] and a third trial enrolling primarily pediatric subjects noted better results with a twice-daily schedule.[78] A retrospective study of allogeneic donors reported that single daily dosing of G-CSF predicted a lower yield of HSCs.[79] Patients, especially those previously treated with chemotherapy or radiotherapy (see later) will generally have lower quantities of CD34+ cells mobilized. However, previous treatment with chemotherapy does not preclude the use of G-CSF. De Luca and colleagues[80] noted a median 76-fold increase in CFU-GM for a population of 30 patients who were previously extensively treated for B-cell malignancies. Older donors will also have lower levels of CD34+ cells mobilized into the peripheral blood after G-CSF administration.[81]

Lymphocytes are also increased in the peripheral blood, and G-CSF priming may change the cytokine response of these cells,[82,83] possibly decreasing the risk of acute GVHD,[84] and augmenting the graft-versus-leukemia effect.[85] The potential influence of these changes in outcome of allogeneic (or autologous) transplantation is not clear.

The toxicity of G-CSF has been most clearly defined in studies of allogeneic donors.[72,73,86,87] The autologous patient will experience a similar toxicity profile, but with the added complications of the underlying malignancy and its treatment. Virtually all recipients of G-CSF will develop somatic complaints, of which skeletal pain is most prominent (Table 60–2). Few serious complications of the mobilization regimen and donation process have been reported.[88,89] Splenic rupture that occurred for a healthy donor appeared to be temporally related to the donation process, and a small study of normal donors showed an average increase in spleen size of 1.1 cm.[90] Filgrastim induces a hypercoagulable state, possibly increasing the risk of vascular events in some patients or donors.[91,92] Patients with autoimmune disorders may experience a flare of their disease during administration of filgrastim.[93] A variety of case reports of ophthalmologic and other adverse events have been reported for healthy donors or patients treated with filgrastim.[94–97] No clinical evidence exists that these agents will induce abnormalities in the hematopoietic cell, and no reports exist of an increased risk of myelodysplasia or hematologic malignancies in either healthy donors or patients who have been treated with short courses of G-CSF.

Table 60–2 Incidence of Somatic Complaints for Healthy Donors Treated with Filgrastim

	Anderlini[86]	Stroncek[73]	Bishop[72]
Number of donors	43	85	41
G-CSF dose	6 μg/kg/d	2–10 μg/kg/d	5 μg/kg/d
Symptom			
Malaise	82	86	83
Headache	70	28	44
Fatigue	20	14	NR
Fever	0	NR	27
Chills	NR	NR	22
Nausea	10	11	22

The reported proportion of donors experiencing the somatic complaint is shown. NR means this particular complaint was not reported in the series.

G-CSF administration results in a number of changes in blood counts and chemistries in addition to the coagulation factor changes noted earlier.[73,86] Alanine aminotransferase (ALT), lactate dehydrogenase (LDH), and alkaline phosphatase levels will increase, and the levels of blood urea nitrogen and bilirubin may decrease. These abnormalities of serum chemistries will resolve within 2 weeks after discontinuation of this medication. G-CSF administration will also result in a decrease in platelet count, especially if the cytokine is administered over many days.[73,87] WBC counts decrease rapidly after discontinuation of G-CSF. In about 10% of donors, the WBC may decrease to abnormal levels (but generally remain >1000 per microliter), reaching a nadir at 10 to 14 days after discontinuation of the cytokine before stabilizing at normal levels.

Cytokine Mobilization with GM-CSF

Much of the early experience with the use of hematopoietic cytokines for the mobilization of HSCs involved GM-CSF and chemotherapy.[32,98,99] The increase in CFU-GM in the peripheral blood can increase by as much as 1000-fold in this setting.[32] Moreover, at least for some patients, the combination of cyclophosphamide and GM-CSF is more effective than mobilization with G-CSF alone.[100] GM-CSF is not as potent as G-CSF, as discussed earlier. Haas and colleagues[101] treated 12 patients with 250 $\mu g/m^2$/day of GM-CSF and observed only an 8.5-fold increase in the number of CFU-GM in the peripheral blood (to a median of 1347 CFU-GM/mL). As with G-CSF, a dose response also occurs in mobilization of PBSCs with GM-CSF over a range of 0.3 to 20 μg/kg/day without a plateau being observed.[102] In this latter study, however, the average increase in CFU-GM in the blood at this highest dose level was again only 8.4-fold. In a randomized study comparing GM-CSF with G-CSF or both drugs used in sequence after chemotherapy administration, patients recovered counts faster, required less supportive care including transfusions, and achieved greater collections of CD34+ cells if given one of the G-CSF–containing regimens.[103] However, administration of GM-CSF (alone or in combination with G-CSF) to healthy donors may result in a lower risk of acute GVHD.[104]

Administration of GM-CSF results in similar somatic complaints and liver-function abnormalities reported after G-CSF administration.[105] In addition, 44% to 80% of patients will experience fever, sometimes after each dose, and generalized or local skin reactions. Lieschke and Burgess[106]

noted that doses greater than 20 μg/kg/day are poorly tolerated because of fluid retention, pleural and pericardial inflammation, and venous thrombosis. A "first-dose reaction" characterized by hypoxia and hypotension occurring within 3 hours after administration has been described for some recipients, especially after intravenous (IV) administration.[107]

Mobilization with Other Hematopoietic Cytokines

Recognition of the mobilization potential of G-CSF led many investigators to study other hematopoietic cytokines for their capacity to mobilize HSCs into the peripheral blood, including M-CSF, interleukin 3 (IL-3), IL-3 and GM-CSF fusion protein, erythropoietin, and stem cell factor (SCF).[108–118] Used as single agents, these cytokines resulted in only about a 5- to 10-fold increase in circulating CFU-GM or CD34+ cells. Moreover, many of these cytokines also caused unique toxicities, and most of these products are not commercially available.

Mobilization with Combinations of Cytokines

G-CSF + GM-CSF: The addition of G-CSF to GM-CSF greatly increases the number of HSCs mobilized. The converse is not true. Winter and others[119] treated patients with a variety of malignancies to regimens of GM-CSF or G-CSF (both at 5 μg/kg/day) to which the other cytokine was added at day 7 of treatment and both continued through day 12. The addition of GM-CSF on day 7 resulted in greater numbers of CFU-GM being collected in subsequent apheresis procedures than were collected on day 5, although the effect was not very great. In contrast, the addition of G-CSF on day 7 to patients treated with GM-CSF resulted in a strong release of CFU-GM 4 days later. Ho and coworkers[120] similarly studied the administration of GM-CSF or G-CSF at doses of 10 μg/kg/day, or both cytokines together at doses of 5 μg/kg/day each and found that G-CSF alone achieved greater mobilization than GM-CSF or both drugs given in combination at a lower dose. Among healthy allogeneic donors, the sequential combination of GM-CSF followed by G-CSF yielded superior CD34+ cell collections compared with GM-CSF at the same dose or concurrent G/GM-CSF.[121] Of interest, however, is the observation that the addition of GM-CSF to G-CSF in the treatment of healthy donors will affect the dendritic cell profile in the collected product, possibly leading to an enhanced antitumor effect and reduced risk of relapse after transplantation.[122]

Other Combinations: The combination of G-CSF with other cytokines such as SCF and IL-3 has also been the subject of clinical studies with additive or synergistic effects being described.[123–131] The combination of erythropoietin with G-CSF has been found to enhance HSC collection in two autologous transplant studies,[132,133] but to be antagonistic in another study involving allogeneic donors.[134] Again, the use of these agents in combination is precluded by the lack of commercial availability.

Mobilization with Chemotherapy Plus Cytokine

Chemotherapy plus cytokine will generally mobilize greater numbers of PBSCs than either alone.[100,135–137] No differences in the degree of tumor cell contamination of PBSC components, engraftment kinetics, or survival were found. A wide variety of different chemotherapy regimens have been used successfully for the mobilization of HSCs into the blood. The primary consideration is that the choice of chemotherapy used must meet the treatment needs of the patient. However, evidence also exists that the choice of chemotherapy regimens will affect the mobilization of HSCs. Schwartzberg and colleagues[138] reported an average daily apheresis yield of 4.0×10^7 CD34+ cells in 395 apheresis components collected from 61 patients treated with cyclophosphamide (CY) and average yields of 8.3×10^7 CD34+ cells in 218 collections from 33 patients treated with both CY and etoposide. (Another group of 24 patients were treated with this latter chemotherapy regimen, but also received 6 μg/kg/day of G-CSF. The average CD34+ cell contents for 122 collections from these patients were significantly higher at 38.8×10^7.) The average quantities of CFU-GM paralleled the numbers of CD34+ cells collected. Similarly, Demirer and coworkers[139] studied the effect of different chemotherapy regimens for the mobilization of HSCs for patients with breast cancer. Four regimens were used, all involving CY, but including etoposide with or without cisplatin, or paclitaxel. All patients also received G-CSF. The median quantity of CD34+ cells collected on the first day of apheresis after CY mobilization was 0.9×10^6 per kilogram of patient weight. The addition of etoposide, and then etoposide and cisplatin increased this to 8.1×10^6 and 3.5×10^6 CD34+ cells/kg, respectively. The median number of CD34+ cells harvested on the first day of apheresis after CY plus paclitaxel was 11.1×10^6 per kilogram. More than 50% of the women mobilized with this last regimen achieved the target dose of CD34+ cells in one apheresis procedure. Of the 100 women studied, 94 achieved the target dose of more than 5×10^6 CD34+ cells per kilogram. Only 4 patients failed to reach a lower but acceptable dose of 2.5×10^6 CD34+ cells per kilogram.

Mobilization with Chemokines

The chemokines are a superfamily of small peptide molecules instrumental in the regulation of leukocyte migration and trafficking. They may be subdivided into four families (CXC, CC, CX3C, and C), with important developmental immunologic and hematopoietic functions, and play a critical role in host defense.[140,141] They mediate their function through specific receptor proteins on the cell surface. Therefore, the interaction of the chemokine with its specific receptor forms an axis that may be manipulated to enhance stem cell mobilization from the bone marrow to the peripheral blood to optimize PBSC harvesting.[142]

Recently the role of the stromal cell–derived factor (SDF-1α) has been intensely investigated in hematopoietic progenitor and stem cells with long-term repopulating capability homing to the bone marrow in humans. Reports suggest that this mobilization effect relies on both the interaction with CCXR4 and its plasma concentration.[143,144] These findings also suggest that functional interaction between SDF-1α, CCXR4, and hematopoietic growth factors is implicated in cell migration. To exploit this effect, antagonists to CCXR4 (CTCE-0021 and AMD3100) have been studied alone and in combination with G-CSF in both murine and human systems to assess mobilizing capacity.[145–147] CTCE-0021 demonstrated both polymorphonuclear leukocyte (PMN) and hematopoietic progenitor cell (HPC) mobilization with a strong dose-effect differential in the two populations; multiday administration favored augmented PMN but not HPC mobilization. Strong synergism with G-CSF existed in the mobilization of both populations, but no alteration of plasma or marrow proteases was noted, and the primary end point of downmodulation of

CCXR4 and disruption of the SDF-1α/CCXR4 axis to induce mobilization was reached. The role of AMD3100 in mobilization of autografts for patients with NHL and MM was recently explored and published. This trial demonstrated that AMD3100 in combination with G-CSF produced a median 2.9-fold increase in circulating CD34+ cells 6 hours after initial dose with higher daily harvest totals, fewer apheresis procedures, early neutrophil recovery after transplantation, and minimal toxicity during mobilization.[148] The precise mode of action of AMD3100 remains to be elucidated. Because of the rapid mobilization engendered by the combination of the AMD31000 and G-CSF, studies are under way to ascertain whether AMD3100 alone may be sufficient to mobilize patients for autologous or allogeneic transplantation.[149]

In a primate study, the administration to rhesus monkeys of a modified CXC chemokine GROβ after 4 days of G-CSF resulted in a fivefold increase in the number of circulating stem and progenitor cells compared with G-CSF alone within a time course measured in hours.[150] The studies with GROβ have been translated to human volunteers where a variant GROβ-T, even though it lacks intrinsic colony stimulating activity, in combination with colony-stimulating factors has been proven to augment synergistically CFU-GM to levels far greater than either agent alone, as well as mobilization of early high-proliferative-potential progenitor cells into the peripheral blood.[151] This phenomenon may be explained by the codependence of the GROβ-T receptor CXCR2 and G-CSF receptors. IL-8 mobilizes stem cells within 15 to 30 minutes of injection into mice, an effect too rapid to result from an increase in the numbers of HSCs in the marrow compartment.[152] IL-8 also exerts its effects via the CCXR2 receptor, and an association between IL-8 levels in the blood and the numbers of CD34+ cells in normal donors undergoing G-CSF mobilization of PBSCs was found by Watanabe and others.[153] Studies are also under way to elucidate the precise role of the Flt3 ligand and its Flt3 receptor on the SDF-1α/CXCR4 axis and its effects on the kinetics of mobilization of both normal CD34+ cells and leukemic clone proliferation.[154]

These studies indicate that chemokines play a definitive role in the enhanced migration (mobilization) of HSCs into the peripheral blood preparatory to initiation of the apheresis procedure. These molecules do not expand the number of HSCs but increase the number available for collection, thereby reducing the volume of blood necessary to be processed to achieve the desired quantity of HSCs.

Management of Mobilization Failure

Most patients achieve the targeted dose of CD34+ cells after the processing of 20 to 30 L of blood in one to three apheresis procedures. However, about 5% to as many as 30% of patients in various series will have inadequate collections because only small numbers of HSCs are present in the peripheral blood despite the administration of hematopoietic cytokines. As discussed earlier, different chemotherapy and cytokine regimens will affect the mobilization of HSCs. Patient-specific factors predictive for poor mobilization include older age, marrow disease, prior radiotherapy, and prior chemotherapy.[29,155–158] The previous administration of marrow-toxic drugs suppresses the subsequent mobilization of HSCs.[159–162] About 50% of patients who fail to achieve the targeted dose of CD34+ cells will achieve this goal on a second attempt,[163] and a second-line harvest of PBSCs may be more efficacious than bone marrow harvesting.[164] High-dose (15 mg/kg BID) G-CSF after a 2- to 4-week drug holiday to allow marrow recovery is one strategy. Combination cytokine therapy is also of potential value in this situation but not adequately explored in clinical trials. An interesting report describes the administration of human growth hormone in combination with G-CSF in a series of 16 hard-to-mobilize patients.[165] Repetition of a chemotherapy-plus-cytokine regimen will also work, but may be associated with increased toxicity.[158] Bone marrow can be harvested, but the poor mobilization of PBSC predicts for a poor marrow harvest.[166] Consideration should also be given to infusing a lower dose of CD34+ cells (as low as 1×10^6 CD34+ cells/kg) because, although the risk of delayed engraftment is incurred,[181,182] failure of engraftment has not been reported.[158,167]

Consideration should also be given to collection of PBSCs early in the course of treatment for patients who may later be candidates for autologous HSC transplantation but who are advised to receive multiple courses of therapy or therapy involving alkylating agents or radiation therapy. HSCs may be collected and cryopreserved before extensive therapy while the patient has good marrow function and stored for years without obvious progressive loss of engraftment potential.[168]

Large-Volume Leukapheresis

The apheresis device has a uniform and fairly reproducible efficiency of collection. Thus, for a consistent quantity of blood processed through the machine, the quantity of CD34+ cells collected is directly related to the number present in the peripheral blood. Greater quantities of CD34+ cells can be collected by increasing the number of these cells in the peripheral circulation or by increasing the volume of blood processed by the device. For those patients with lower CD34+ cell levels, multiple apheresis procedures will be required to achieve the target dose of CD34+ cells needed for transplantation. An alternate approach is to process the same total quantity of blood, but in fewer, longer procedures. Large-volume leukapheresis (LVL) is not standardly defined, but in general use refers to the processing of more than 2 or 3 times the patient's blood volume.[169–178] Typically, the quantity of blood processed is 6 or more times the patient's blood volume, often 25 to 36 L of blood. The advantage of LVL is that this reduces the number of days of cytokine administration and apheresis with associated reduced costs of laboratory processing and testing. The apheresis techniques are the same as used for the processing of smaller volumes of blood, although blood flow rates may be increased to reduce the time required. The risks of LVL are the increased time required and the higher risk of citrate (or other anticoagulant) toxicity. Patients will also incur a proportional decrease in platelet counts and may become profoundly thrombocytopenic.

Most reports of LVL describe the collection of more CD34+ cells than are calculated to be present in the peripheral blood at the initiation of the apheresis procedure. Obviously, release of cells from the marrow replaces those removed by apheresis. Apheresis of CD34+ cells is a three-compartment system consisting of the extracorporeal circuit of the apheresis device (including the collection bag), the peripheral blood, and the marrow. However, it is not obvious that the apheresis technique itself consistently "mobilizes" CD34+ cells. The experience with patients and donors treated with cytokines or chemotherapy-plus-cytokine is variable, with reports describing an increase,[171–175] no change,[169,177,178] or even an exhaustion of CD34+ cells from the peripheral

blood.[177,179] An increase also may not be evident in patients with poor marrow function.[176]

Clinically, most important is the possibility of exhaustion of HSCs such that the processing of the large blood volumes exposes the patient to the risks of anticoagulant toxicity and thrombocytopenia without achieving an increased collection of HSCs. However, studies at the Fred Hutchinson Cancer Research Center demonstrated a continuous release of CD34+ cells from the marrow (and, presumably, return to the marrow space).[180] Patients having higher levels of CD34+ cells in the peripheral blood appeared to have a greater number of these cells circulating between the marrow and peripheral blood compartments. In this model, the apheresis device merely serves as a siphon, removing these cells from the blood as they are released from the marrow. If this is an appropriate description of CD34+ cell kinetics, it may be possible to deplete these cells from the blood and marrow by prolonged processing, but probably only if limited numbers of these cells are in the marrow compartment. Also, the model suggests that higher blood flow rates used to shorten the apheresis procedure may be counterproductive for the patient with low CD34+ cell levels in the blood because of the slower rate of release of CD34+ cells for these patients.

LVL is appropriate management for the patient or donor who needs to complete apheresis in a limited number of procedures. The quality of the component collected by LVL does not differ from that collected by the processing of smaller volumes of blood, and patients experience the same rapid kinetics of engraftment after infusion of these components.[174]

Definition of Adequate Component(s)

The quantity of CD34+ cells in a PBSC component varies greatly and is dependent on the number in the peripheral blood at the time of collection and the volume of blood processed. Therefore, any definition of an adequate component cannot include a set number of CD34+ cells in a single apheresis component. Instead, one or more components will be collected to meet the appropriate dose of these cells for transplantation. What dose of CD34+ cells is required for infusion depends on the intended treatment regimen. For marrow-ablative regimens, increasingly higher CD34+ doses results in greater likelihood of rapid engraftment.[181,182] Although most transplant centers will probably accept components containing at least 1×10^6 to 2×10^6 CD34+ cells per kilogram of recipient weight, cell doses of 2.5×10^6 to 5×10^6 CD34+ cells per kilogram are desirable, and quicker engraftment will even be observed with higher doses.[181,182] Administration of G-CSF after transplantation will further speed the recovery of granulocytes[183–185] but may have a detrimental affect on platelet engraftment for patients receiving components containing low numbers of CD34+ cells.[181]

At lower doses of CD34+ cells, considerable heterogeneity is found in engraftment speed, especially for platelet engraftment. It is not known why this heterogeneity exists, but it may reflect a weakness in the correlation between CD34+ cells and the cells responsible for engraftment, or more simply, a greater degree of error in the measurement of CD34+ cells at the lower cell concentrations. As the dose of CD34+ cells increases, the engraftment speed becomes more consistent for the population studied.[181,182] Several investigators showed more rapid granulocyte and platelet engraftment for recipients of products containing a quantity of CD34+ cells above a dose of about 2 to 3×10^6 per kilogram recipient weight.[156,157,186] Investigators at the Fred Hutchinson Cancer Research Center found a threshold of 5×10^6 CD34+ cells per kilogram to achieve reliably prompt platelet engraftment,[187] and studies that include large patient populations found that higher doses of CD34+ cells will result in even higher proportions of patients achieving quick engraftment.[182] Investigators at the Hutchinson Center noted that the dose of CD34+ cells infused was more important than the type of mobilization therapy. In a study of allogeneic transplant recipients, Singhal and colleagues[188] reported a higher transplant-related mortality for patients who received a CD34+ cell dose less than 2×10^6 per kilogram, regardless of source of HSCs.

A major problem with chemotherapy-based mobilization regimens is the difficulty in determining the optimal time to commence HSC collection. Although many protocols call for the initiation of apheresis when the WBC count has recovered to greater than 1000 per microliter, a poor, if any, correlation exists between the peripheral blood WBC counts and the CD34+ cells in the peripheral blood. Characteristics that suggest a higher CD34+ cell level are rapidly increasing WBC count, a shift in differential to immature myeloid cells, circulating nucleated red cells, and platelet transfusion independence. These features may be more valuable in a homogeneous patient population receiving a uniform mobilization regimen.[189] However, it may be cost effective to obtain an actual measurement of CD34+ cells in the blood for the timing of apheresis collection. The published experience from many transplant centers describes a correlation between the CD34+ cells in the peripheral blood and in the harvested component.[156,186,190,191]

At what level of CD34+ cells in the peripheral blood to start apheresis is a clinical decision. Although levels in the range of 50 to 100/μL or greater will reduce the number of apheresis procedures necessary to achieve a target goal of CD34+ cells, each day's delay in initiating apheresis also incurs the costs of additional cytokine administration and blood testing. For some patients who have been extensively treated, it may be necessary to accept multiple apheresis procedures to achieve the target goal. Certainly, no patient should undergo apheresis if the peripheral blood count is less than 5 per microliter. For patients with CD34+ cell counts in the range of 10 to 20 per microliter, it is possible to process more blood per day by using LVL techniques. Most patients will have an increasing CD34+ cell count in the peripheral blood, so it is generally feasible to start apheresis the day after the patient has achieved a desirable CD34+ level.[191]

The timing of apheresis after G-CSF mobilization differs from the timing after chemotherapy and cytokine mobilization. For both patients and healthy donors, the peak concentration of CD34+ cells occurs on the fifth day of G-CSF administration (after four daily doses).[70,71] Lower levels are present on day 4, and the concentration continues to decrease after day 6 even if cytokine administration is continued and despite a continued increase in the WBC count. Thus, PBSC collection should be initiated on day 4 or 5 of G-CSF administration. The kinetics of CD34+ cells in the peripheral blood for patients and donors mobilized with G-CSF alone are so reliable that it is not necessary to monitor peripheral blood levels unless concern is felt that the patient has failed to mobilize cells and it is practical to obtain the cell count rapidly enough to initiate apheresis on the same day.

Evaluation of the Peripheral Blood Stem Cell Donor

The PBSC donor must meet the same donor health criteria applied to the bone marrow donor. The unique considerations for the PBSC donor are the need for adequate venous access and the risks of cytokine administration. The risks of cytokine administration are unique to each drug and are described earlier in this chapter. Anderlini and coworkers[88] suggested that G-CSF specifically not be administered to patients with a history of inflammatory ocular disorders, venous thrombosis, autoimmune disorders, or malignancy treated with chemoradiotherapy. Beelen and colleagues[192] reported in an interim analysis of an ongoing study of healthy donors receiving one of two different doses of G-CSF that 478 acute adverse events were noted in the first 150 donors enrolled. Most (80%) of these adverse events were transient bone pain or headache, and no persistent hematologic or nonhematologic events were recorded.

Older donors will have more underlying medical conditions, and the risks to the donor with underlying health problems must be fully considered before subjecting the donor to mobilization and apheresis.[193] The special challenges of the pediatric patient arise from the fixed extracorporeal blood volume of the apheresis device, the need for venous catheters for blood access, and the management of a patient who may be unwilling or unable to rest quietly for the period of apheresis. Virtually all pediatric patients undergo insertion of a venous catheter adequate for the flow rates expected, although older (older than 12 years) patients may tolerate vein-to-vein procedures. The whole blood flow rate for the pediatric patient is much reduced compared with that in adult patients, and catheters as small as 5F be adequate.[205]

Appropriate management of fluid balance during the apheresis procedure is critical for the smaller patient. The volume of red blood cells contained in the extracorporeal circuit of continuous flow apheresis device could represent 30% to 50% of the red cell mass of a pediatric donor. The obvious solution to this problem is to prime the apheresis device with ABO-compatible, irradiated, red blood cells (leukocyte depleted and CMV-negative blood may also be desirable) when the blood in the extracorporeal circuit is expected to exceed 15% of the patient's blood volume.

Complications of Peripheral Blood Stem Cell Collection

Apheresis technology is widely used for the collection of platelets from healthy donors and is considered to be without major risk to the donor. The important safety considerations for PBSC collection are the same as for platelet collection and include the venous access to be used for the procedure, the extracorporeal volume of blood during the procedure, and the solutions administered to the donor. However, it must also be acknowledged that PBSC collection for autologous transplantation involves patients with underlying medical conditions who may require considerable nursing care during the procedure. In a retrospective review of more than 5000 patient plasmapheresis procedures for the treatment of a variety of diseases, complications of apheresis were observed in 12% of procedures, and 40% of patients experienced at least one complication during a course of therapy.[194] Most of these were mild and transient, such as fever, chills, urticaria, hypotension, and reactions to citrate anticoagulants. In contrast, patients and donors undergoing PBSC collection do not require the replacement fluids used during plasmapheresis and will not experience the toxicities associated with plasma protein infusions. However, rare anaphylactic reactions may occur for the pediatric patient who requires blood priming of the extracorporeal circuit, patients treated with angiotensin-converting enzyme (ACE) inhibitors,[195] or those allergic to ethylene oxide used to sterilize the apheresis disposable set.[196] Goldberg and colleagues[197] studied the complications occurring during 554 PBSC collections from 75 consecutive patients. Patient diagnoses were varied, as were the mobilization treatment regimens. All but one patient had subclavian or jugular venous system catheters placed for apheresis. A median of 9 collections per patient was performed by using a discontinuous-flow apheresis device. The most common problems were related to the venous catheters, with 50% of the patients developing at least one occlusion. Hypocalcaemia occurred in 14.6% of patients and hypotension in 13.3%. Sixteen percent of patients experienced infectious complications during the PBSC collection period.

The discomfort, pain, and high levels of anxiety produced by PBSC donation has been rated as equivalent to that experienced by marrow donors enrolled in two randomized trials comparing marrow with PBSC transplantation. However, the PBSC donors reported more-rapid resolution of symptoms.[198,199] To the contrary, Switzer and associates[200] conducted a National Marrow Donor Program (NMDP) retrospective analysis of donor experiences that underwent PBSC donation after a prior bone marrow donation. These donors found the marrow harvest procedure physically more difficult, time consuming, and inconvenient. The comparative risks attendant to the allogeneic PBSC donor and platelet donor should not differ greatly if the apheresis techniques are similar, even though the PBSC donor may undergo larger volume and repetitive exchanges with different anticoagulants compared with the platelet donor. Although platelets can be separated from the component for infusion back to the donor, LVL and repetitive exchanges will result in platelet depletion.[73,86] The platelet count may reach its nadir several days after the completion of the apheresis collections and discontinuation of G-CSF, and donors should be counseled in this regard.[73,87]

Venous Access

Adequate venous access is required for optimal apheresis technique. Therefore, consultation with apheresis unit staff about the suitability of a particular type of venous access for an individual patient/donor is appropriate before commencement of treatment. Continuous-flow apheresis devices require dual-lumen access with a stable blood-flow capacity in the range of 60 to 100 mL/min.[201] Approximately 90% of adult allogeneic PBSC donors have adequate antecubital venous access for the procedure to be conducted "vein-to-vein." Consecutive day procedures may be performed, with scrupulous phlebotomy technique. Autologous transplant patients will have received previous chemotherapy or are proceeding directly to transplantation with tunneled access commonly placed. Often, this venous access can be appropriate both for the apheresis procedures and the subsequent transplant. A short, stiff, tunneled catheter or a temporary percutaneous dialysis/apheresis catheter is an appropriate choice.[202–204] Catheters of 10F or larger size are appropriate for adult patients. Pediatric patients whose blood flow rates are considerably slower may use catheters of 5F to 7F size.[205]

Venous-access complications account for a considerable amount of the toxicity associated with PBSC collection. Mobilization with either G-CSF or GM-CSF is associated with an increase in the incidence of catheter occlusion.[206,207] Goldberg and colleagues[197] reported this complication in 50% of patients. In contrast, Alegre and associates[203] reported only a 1.8% incidence of thrombosis or clotting of catheters, possibly because of differences in cytokine or catheter type and care. Catheter thromboses are easily managed with streptokinase, urokinase, or recombinant tissue plasminogen activator (rt-PA) instillation by the apheresis unit staff. One randomized study reported that low doses of warfarin decreased the incidence of venous thrombosis associated with indwelling catheters, but this study did not address catheter patency, nor were the patients enrolled in this study treated with hematopoietic cytokines.[208] Because of the rare but serious complication of heparin-induced thrombocytopenia (HIT), some centers avoid the use of heparin in favor of saline flushes. A study by Stephens and coworkers[209] demonstrated that the rate of catheter occlusion by thrombosis was similar, irrespective of the use of heparin or saline.

Anticoagulation

Anticoagulants are added to the blood during apheresis to prevent clotting of the extracorporeal circuit and clumping of cells in the component. Citrate (ACD-A) is the most widely used anticoagulant in apheresis procedures for the collection of PBSCs. The major drawback is the risk of a symptomatic hypocalcemia ("citrate toxicity"), especially during LVL.[210,211] ACD-A chelates calcium and magnesium, lowering the serum levels by as much as 35% and 56%, respectively, in inverse proportion to serum citrate levels, thus rendering them unavailable for Ca^{2+}-dependent metabolic reactions. Citrate redistribution throughout the circulation combined with metabolism by liver, kidney, and muscle is instrumental in preventing citrate toxicity.[212] Alterations in electrolytes, plasma protein levels, muscle mass, or renal or hepatic function that may occur for patients receiving chemotherapy may predispose patients to citrate toxicity. The initial signs include circumoral or acral paresthesias and may progress to nausea, vomiting, loss of consciousness, tetany, and seizures. Rarely, fatal cardiac dysrhythmias have been reported for patients undergoing plasmapheresis.[213] Citrate infusions may depress myocardial function, and this may be exacerbated by the concomitant use of calcium channel blockers, although reports of such complications for patients or donors undergoing apheresis have not been published.[210] Pediatric patients may not be able to relate the initial symptoms of citrate toxicity, and this should be considered for any change of behavior such as crying for these patients during the apheresis procedure. Prevention of citrate toxicity is by limiting the quantity of citrate infused either by decreasing the blood flow rate through the apheresis device or changing the blood-to-citrate ratio. The processing of blood of patients experiencing the initial symptoms of citrate toxicity should be temporarily halted until the symptoms abate and then resumed at a slower rate. Heparin may be used as a replacement for some or all of the citrate, although additional citrate is added to the component bag to prevent clumping of platelets.[33,214] Some centers using citrate anticoagulants will also administer intermittent or continuous infusions of calcium gluconate during the procedure, especially if large volumes of blood are being processed.[169] Buchta and colleagues[215] have suggested that female donors with total blood volume of less than 4.5 L may be ideal candidates for calcium administration. However, excessive calcium replacement can also induce cardiac dysfunction.[210]

PROCESSING OF HEMATOPOIETIC STEM CELLS

Management of Red Blood Cell Incompatibility

Management of red blood cell incompatibility is the same for PBSCs and bone marrow transplantation.[216] The infusion of incompatible red blood cells or immunocompetent B lymphocytes may provoke acute or delayed hemolytic transfusion reactions; therefore, red cell and/or plasma depletion may be required, and careful transfusion practices are critical. Red cell incompatibility may be classified into two major categories. First, major incompatibility is the situation in which host antibodies directed against infused donor red cells may produce acute hemolysis. Red blood cell quantities of 10 mL or less appear to be tolerable, although no safe level can be defined. Most PBSC components will contain small amounts of red blood cells, and apheresis devices are commonly used to remove red cells from marrow products.[217] Second, minor incompatibility is the situation in which donor-derived antibodies exist or may develop against the recipient. Although the latter rarely causes immediate infusion reactions, B lymphocytes within the component can form isoagglutinins, resulting in a delayed transfusion reaction 7 to 12 days after transplantation. Minor ABO incompatibility can result in delayed transfusion reactions that are potentially fatal if appropriate blood-transfusion support (avoiding the infusion of donor-type red cells) is not initiated before the transplant. Some authors suggest that the much greater numbers of B cells in PBSC products increase the risk of delayed hemolysis in the setting of minor ABO incompatibility.[218] However, the risk of delayed-type reaction may be reduced by the use of multiple post-transplant immunosuppressive medications, and the Seattle transplant program reported no delayed transfusion reactions in a large retrospective review of patients undergoing PBSC transplantation with cyclosporine and methotrexate immunosuppression.[219] Some patient/donor pairs may be incompatible with each other (bidirectional incompatibility) and must be managed by using the strategies for both major and minor red blood cell incompatibility.

Red cell depletion of bone marrow products is usually accomplished by centrifugation with or without the addition of hydroxyethylstarch,[220,221] or by processing of the product through an apheresis device.[222,223] The goal of processing is maximal recovery of HSCs with maximal depletion of red blood cells. At least 80% of nucleated cells should be recoverable through centrifugation; processing using an apheresis device may result in a relative enrichment of mononuclear cell fraction including HSCs and lymphocytes. PBSCs collected through apheresis technology already contain a small quantity of red blood cells, and further processing is more likely to result in cell losses without benefit. Plasma depletion is often performed for minor red cell incompatibility and is achieved through simple centrifugation of the product.

Tumor Cell Purging of Hematopoietic Stem Cell Components for Autologous Transplantation

The probability that tumor cell contamination of the component could contribute to relapse was demonstrated by Brenner and others[224–226] in studies involving the transplantation of genetically marked marrow cells. As a corollary to this, van Besien and colleagues[227] and Bierman and colleagues[228] suggested that tumor-free grafts may improve outcomes. Sensitive immunocytostaining techniques, clonal assays, flow-cytometric analysis, and polymerase chain reaction (PCR) amplification of malignant genetic material detect tumor cells in the PBSC components of many patients with a variety of malignancies.[229–232] In general, the incidence of contamination and the level of contamination is much less for PBSCs than for marrow components,[229] although this has not been a consistent finding in all studies.[230] In light of the clinical advantages of autologous PBSC transplantation, a phase III study to assess the relative relapse rates of PBSC versus bone marrow transplantation is unlikely to be conducted without preliminary evidence justifying the randomization of patients to the bone marrow transplant control arm. In a retrospective study, Sharp and associates[233] demonstrated similar probabilities of relapse-free survival for recipients of PBSC or marrow components if the HSC products were free of lymphoma cells. In that study, patients with marrow involvement by lymphoma were assigned to transplantation with PBSCs, suggesting that PBSC collection is a sensible approach to the patient with overt marrow involvement. Brugger and coworkers[234] however, demonstrated that patients with breast cancer involvement of the marrow at the time of chemotherapy mobilization were just as likely to mobilize tumor cells as CD34+ cells into the blood. Similarly, Pecora and colleagues[235] found a relation between the ability to detect tumor in PBSC components and in bone marrow samples, but also found a higher incidence of positive PBSC components for patients who required greater numbers of apheresis procedures to achieve the target dose of CD34+ cells. Investigators at The Johns Hopkins Oncology Center found no difference in the incidence of tumor contamination of PBSC components between patients mobilized with chemotherapy plus cytokines versus cytokines alone.[236] Because the probability of tumor contamination of PBSC components decreases after induction chemotherapy,[237] patients with marrow involvement should benefit from several cycles of debulking (in vivo purging) chemotherapy before collection of PBSCs with the caveat that extensive chemotherapy will decrease the subsequent yield of PBSCs. This concept was demonstrated in a randomized study comparing precollection treatment of patients with non-Hodgkin's lymphoma with rituximab to postcollection purging of the PBSC product.[238] The PBSC products for both patient groups were equally likely to be tumor cell positive and to achieve similar event-free survivals, but the products that were purged contained fewer CD34+ cells, and patients receiving the purged components experienced delayed hematologic recovery.

Considerable effort has been devoted to the development of purging techniques based on physical characteristics, immunologic differences, or relative sensitivities of normal and malignant cells to chemotherapeutic agents. PBSC components can be purged of tumor cells by using the same techniques originally developed for marrow, although the larger cell quantities collected and the multiple days of collection will increase the cost of this processing. The commercial availability of devices that enrich CD34+ cells has served to focus recent purging studies on this technology. The presence of this marker on hematopoietic stem and progenitor cells enables the enrichment of these cells from the HSC product. The enriched populations can then be used for transplantation or for further manufacturing, such as gene therapy or cell expansion. Numerically, simple enrichment of CD34+ cells from less than 1% to levels of 70% to 95% results in a greater than 90% to 99% depletion of CD34− cells, leading many investigators to explore CD34+ cell enrichment as a technique of T-cell depletion to prevent GVHD in allogeneic cell recipients,[239–242] or tumor depletion to decrease the risk of relapse for autologous component recipients.[243–246] Engraftment does not appear to be affected by the CD34+ cell enrichment unless low quantities of CD34+ cells are infused.[243]

Positive enrichment of HSCs achieves nonspecific tumor cell depletion as CD34+ cells are separated from the antigen-negative cells. Because this depletion is nonspecific, the degree of purging achieved will equal the depletion of other CD34− cells such as lymphocytes. Typically, this will range from 99.0% to 99.99% depletion. By itself, CD34+ cell enrichment will reduce the number of tumor cells below the level of detection of some assay systems. For example, Shiller and colleagues[243] reported that five of eight components were negative for myeloma cells after processing, but Lemoli and associates[246] found the persistence of detectable disease in five of six patients tested. The median purity of the CD34+ cells was actually greater in the latter study (77% vs 89.5%). Phase III studies of CD34 enrichment for patients undergoing treatment for myeloma show the feasibility of CD34+ cell enrichment of PBSC components, although these studies were not powered to demonstrate efficacy in control of disease.[247] In an effort to improve the specificity of purging, some investigators have used a double-purging technique. Altes and coworkers[248] used a positive CD34 and negative CD19 double-selection method to improve the efficacy of single purging in 26 patients with a poor prognosis in lymphoproliferative disorders with minimal residual disease (MRD) detected by PCR and flow cytometry. Half of the patients mobilized an adequate number of CD34+ cells and proceeded into the double-purge arm. Twelve harvests became PCR negative after double selection, and 10 patients were autografted. At a median follow-up of 30 months, only 2 patients had molecular relapse. However, a high frequency of life-threatening infections was found in this study, underscoring the risks associated with this double-enrichment modality. A recent study of double-enrichment technique (based on CD34 and CD133 expression) reported a 50% improvement in tumor cell depletion, but clinical studies have not yet been reported.[249] No benefit for survival has been shown in any randomized study of ex vivo purging (Table 60–3).[238,247,250,251]

T-Cell Purging of Hematopoietic Stem Cell Components for Allogeneic Transplantation

Effective removal of mature T lymphocytes from the stem cell inoculum can reduce both the incidence and the severity of acute and chronic GVHD. A number of depletion techniques have been developed, including physical techniques such as elutriation or agglutination; and antibody-based techniques involving complement-mediated killing, solid-phase separation, or the more recently developed CD34+ cell-enrichment techniques that nonspecifically separate T

*Initial data published in Vescio, R, Schiller G, Stewart AK, et al. Multicenter phase III trial to evaluate CD34+ selected versus unselected autologous peripheral blood progenitor cell transplantation in multiple myeloma. Blood 1999;93:1858–1868.

lymphocytes and other CD34− cell populations from the CD34+ stem cell population. The intent of these procedures is to deplete mature T lymphocytes from the stem cell inoculum. The occurrence of GVHD decreases as T-cell quantities are reduced below 10^5 per kilogram of recipient weight.[252]

The major risks of T-cell depletion are widely recognized and include loss of the graft-versus-tumor (GVL) effect with increased risk of disease relapse, increased risk of infections if delayed immunologic reconstitution results from the depletion method used, and failure of engraftment or graft rejection. Higher doses of HSCs, which can be achieved by combining marrow and PBSC components, will reduce the risk of graft failure.[253] Fixed doses of lymphocytes, as opposed to maximal T-cell depletion, may also reduce the risk of graft failure.[254] The clinical benefit of reduced GVHD may be offset by the complications of T-cell depletion. A large, multicenter, randomized trial that enrolled more than 400 patients found more rapid engraftment for the recipients of T-depleted grafts (who did not receive post-transplant methotrexate), fewer grade III to IV nonhematopoietic toxicities, shorter hospitalization, and a lower risk of severe acute GVHD.[255] However, the recipients of the T-depleted grafts experienced higher likelihood of infectious complications and relapse, and overall survival at 3 years after transplantation did not differ statistically (27% for T-depleted recipients; 34% for control group). This study also found no difference in the risk of chronic GVHD,[256] and economic analysis found no difference in the costs of transplantation with the reduced costs from not treating acute GVHD offset by the increased costs of treating serious infections.[257]

QUALITY CONTROL OF HEMATOPOIETIC STEM CELL PRODUCTS

Microbial Contamination of Hematopoietic Stem Cell Components

Bone marrow harvesting, by virtue of the procedural techniques, has a risk of contamination of the product by bacterial skin flora. However, this contamination is, generally, not a cause of clinically significant infections in the recipient, although some serious infections have been reported from contamination of products during postharvesting processing.[258–264] Any decision regarding the disposition of culture-positive HSCs must be made by the patient's transplant physician after considering the type of contamination, the anticipated risks from use of the component, and the ability to replace the culture-positive component(s) in a timely manner. As a consequence of the different collection modality, the incidence of contamination of PBSC products is considerably less than that for marrow.[262–264] Attarian and colleagues[168] reported only 3 products with bacterial contamination in a prospective study of 1263 PBSC collections from 376 sequential patients, even though 50% of the patients were receiving antibiotics for the treatment of neutropenic fever on the day of apheresis. Clinically stable but febrile patients may safely have PBSCs harvested based on the kinetics of mobilization of CD34+ cells into the peripheral blood. Bone marrow harvesting, the timing of which is not determined by cytokine administration, should be delayed for the comfort and safety of the donor.

Quantitation of CD34+ Cells

Quantification of CD34 antigen-positive cells by flow cytometry has become the standard of care for the management of the PBSC donor because it provides a rapid and clinically relevant assessment of HSC content in the peripheral blood or the PBSC component. Cell viability using propidium iodide (PI) or 7-aminoactinomycin D (7-AAD) exclusion can simultaneously be determined if the cells are analyzed while still fresh.[265] Many centers are finding strong correlations between the numbers of CD34+ cells and CFU-GM in the sample, but with a ratio of about 520:1.[190,266] Thus, CD34 analysis will provide data similar to those obtainable with cell cultures, with the exception that the growth of cells in the laboratory demonstrates the viability of the progenitor cells.

The major difficulty with the analysis of CD34+ cells is the low frequency of these cells. This enumeration is possible because of the multidimensional measurements possible with the flow cytometer, which can measure at least five characteristics of each cell including size, granularity, and the presence of up to three different fluorochromes. Thus the cells of interest can be separated in five-dimensional space, achieving discrimination of cells as rare as 1 in 10,000. The difficulties arise from developing an adequate technique that makes optimal use of the cytometer to measure these rare cells. Sources of errors include (1) sampling of the component, (2) cell counting, (3) cytometer calibration and operation, (4) choice of antibody and fluorochrome, (5) lysis technique, and (6) gating strategy. The steps involved in preparing a specimen for cytometry may alter the proportion of cells in the sample, and this error will be translated into an error in

the absolute number.[267] Serke and colleagues[268] found a coefficient of variation of 30% in counting of CFU-GM colonies and of 10% in flow-cytometric counting of CD34+ cells. The coefficient of variation in CD34+ cell enumeration could be as high as 65% for specimens containing few cells, and this variation was decreased by the analysis of larger cell samples. A variety of different cytometry techniques are used in measuring CD34+ cells.[269–271] Considerable variation is found in results even between laboratories using the same cytometry technique, and no cytometer-based technique has proven to have a lower interlaboratory variability.[270]

Subset analysis will provide additional information but does not appear to be clinically useful at this time. Pecora and associates[272] reported that the quantity of CD34+CD33– cells infused was identified as an independent factor predictive of engraftment kinetics. Derksen and coworkers[273] reported better correlation between the number of CD34+CD33– cells and time to granulocyte engraftment and between the number of CD34+CD41+ cells and time to platelet engraftment than found with the overall number of CD34+ cells. This group reported a similar finding for the number of CD34+ L-selectin+ cells infused and platelet engraftment.[274] Given the limited range in recovery times when adequate numbers of CD34+ cells are collected and infused, however, this additional information is of limited clinical value.

Progenitor Cell Cultures

Unlike other measures of component quality, progenitor cell cultures also demonstrate the functional capacity of the cells. These techniques require expertise and equipment not available in many clinical laboratories, and have other drawbacks that may limit their utility as routine quality control. Other than availability of equipment and expertise, the major limitation is that progenitor cell assays require 10 to 14 days of culture before the results are available. Thus, progenitor cell cultures cannot be used in the day-to-day management of the PBSC donor. No standard culture technique has been adopted by all laboratories. The clinical relevance of the culture technique to the transplant population must be determined if the data obtained are to be used in the management of individual patients. Progenitor cell cultures are the only currently available relevant assay of HSC viability other than actual engraftment of the recipient, and should be available at the PBSC processing facility for use in quality control or if questions about the viability of a particular component are raised.

STORAGE OF HEMATOPOIETIC STEM CELL PRODUCTS

Cryopreservation

HSCs harvested from the peripheral blood, bone marrow, or umbilical cord blood are frozen and stored by using the same techniques. The general parameters include cryopreservation in dimethylsulfoxide (DMSO) and a source of plasma protein with or without hydroxyethylstarch (HES), cooling at 1° C to 3°C per minute, and storage at −80°C or colder.[275] Variations on this technique include the concentration at which the cells are frozen, the amount and source of the plasma protein, and the cooling techniques used.[276,277] Most of these variations probably have little effect on the survival of the HSCs, but cryopreservation results in the loss of an undefined but potentially substantial proportion of HSCs. Delay in engraftment can occur if the component being frozen has borderline quantities of HSCs.[278,279] A considerable incidence of generally minor toxicity is associated with the infusion of cryopreserved cells.[280]

PBSCs differ from marrow components because of their much larger cell quantity, frequently exceeding 4×10^{10} cells. Cryopreservation of these cells at a set cell concentration, especially if multiple days of collection are performed, may result in large volumes of cryopreserved material to be infused. DMSO itself has a variety of pharmacologic effects,[281] which may be compounded by the presence of lysed blood cells, foreign proteins from tumor-cell purging procedures, or contaminants from nonpharmaceutical grades of reagents used in the processing. The acute toxic dose of DMSO for humans has not been determined. One report cited two instances of encephalopathy after the infusion of cryopreserved PBSC products, possibly containing more than 2 g DMSO per kilogram patient weight.[282] For these reasons, the volume of DMSO infused should be limited to 1 g/kg/day. Patients with larger volumes can receive the cells over more than 1 day.

To minimize the volume infused, PBSCs and bone marrow may be concentrated before cryopreservation. In one series, the average cell concentration of cryopreserved PBSCs was 5.59×10^8 nucleated cells per milliliter.[283] No detrimental effect of cryopreservation at these high cell concentrations on the recovery of nucleated cells, mononuclear cells, or CD34+ cells was found. No clinical studies have addressed the effect of cell concentration during cryopreservation of bone marrow or PBSCs on engraftment speed. Of concern, however, is that several patients infused at that center developed alterations in mental status, including seizures, after infusion of PBSCs concentrated before cryopreservation.[284] It is very unlikely that these events were related to the small volumes of DMSO infused but may be related to the concentration of cells frozen.

HSCs can be frozen in solutions using reduced concentrations of DMSO. A large (294 patients) randomized phase III study comparing engraftment after autologous transplantation of PBSCs frozen using either 10% DMSO or 5% DMSO with 6% HES showed faster granulocyte recovery for patients receiving cells frozen by using the combination cryoprotectant solution.[285] No difference in platelet-recovery speeds was found, suggesting a lineage-specific benefit. These investigators did not report on infusion-related toxicity, although others have suggested that infusion-related toxicities are, in general, proportional to the quantity of DMSO infused.[286]

Alternately, the cells can be washed after thawing, with removal of most of the DMSO.[287] The risk is again one of cell loss, and it is preferable, if possible, that a strategy be adopted to ensure that not all cells are at risk during a single processing. An effect of post-thaw washing on the speed or success of engraftment after infusion of marrow or PBSC components has not been published.

Nonfrozen storage

HSCs may be kept in nonfrozen conditions for transportation or before infusion or subsequent processing. Nonfrozen storage is a less costly alternative to cryopreservation and allows greater flexibility in timing of transplantation relative to HSC collection, including the ability to modify or postpone a transplant-conditioning regimen already started.

A progressive loss of HSCs occurs during nonfrozen storage. One author reported a 61% loss of myeloid colony-forming progenitor cells (CFU-GM) from marrow after 72 hours of storage at 4°C.[288] Yet another found only a 3% loss of CFU-GM from marrow stored for 96 hours, but a 95% loss if the source of the cells was peripheral blood.[289] Preti and colleagues[290] compared the survival of mature hematopoietic progenitor cells isolated from marrow during frozen or nonfrozen storage, and reported an immediate loss of myeloid (CFU-GM) progenitors of 33% during cryopreservation and thawing. In contrast, cells stored at 4°C showed a progressive, linear loss of total nucleated cells, cell viability, and HSCs cloned in vitro. The quantity of erythroid colony-forming progenitor cells (BFU-E) in these nonfrozen samples became significantly less than those in cryopreserved samples only after 5 days of storage. The difference for myeloid progenitor cells (CFU-GM) was not yet significant even after 9 days of storage. These differing reports demonstrate that storage conditions such as concentration of cells, chemicals added, product volume, storage bag, and temperature of storage will affect the survival of cells kept in nonfrozen storage.[291]

Most published reports of noncryopreserved storage describe storage at 4° C, which provides a stable temperature compared with storage at ambient temperatures. The optimal storage temperature is unknown and will probably depend on such concerns as the prestorage processing, the quantity and concentration of mature blood cells, the buffering capacity of the solution, and the gas-diffusion capacity of the storage container. Beaujean and associates[292] for example, reported a greater acidity for PBSC products stored overnight at room temperature compared with storage at 4° C, although they did not find a difference in the recovery of progenitor cells. Storage conditions for nonfrozen storage have not been tested in an engraftment model, so proper storage conditions are not adequately defined. For laboratories intending to store stem cell products, particularly PBSC components, for prolonged periods without freezing, rigorous validation of the storage conditions must be performed.

REGULATORY ASPECTS OF STEM CELL COLLECTION AND PROCESSING

The regulation of the wide range of cellular- and tissue-based products being developed requires either an extensive number of focused regulations specific for each possible product or an adaptable regulatory strategy that can encompass a broad and expanding range of products and manufacturing techniques. The Food and Drug Administration (FDA) proposed in 1997 a new approach for the regulation of cellular- and tissue-based products by using a continuum of regulation that is intended to enable the FDA to meet its task of protecting public health without being unfair to specific practitioners of this field of medicine or stifling to the development of novel uses of these products. These regulations were implemented in May 2005.[9] The intended rigor of control is proportional to the extent of risk involved with use of the tissue or cellular product, with the level of regulation dictated by the following five considerations: prevention of disease transmission, processing controls to prevent contamination and maintain product integrity and function, clinical safety and efficacy, labeling and promotion of the products, and communication with and monitoring of the tissue industry. The regulatory approach taken by the FDA addresses facility registration, selection and evaluation of the tissue donor, and manufacturing of the product. The FDA views cell processing to be a manufacturing activity. Therefore, the FDA expects that the collection, processing, and distribution of HSC-derived components will comply, at least, to current Good Tissue Practices (cGTPs) with the much more detailed current good manufacturing practices (cGMPs) required for extensively manipulated products. cGMPs and cGTPs differ in the level of control over the manufacturing pathway required to prevent contamination or loss of potency of the final product. The FDA developed part 1271 of chapter 21 of the CFR for these regulations. Part 1271 does not replace cGMP regulations for drugs and medical devices found elsewhere in Chapter 21 of the Code of Federal Regulations (CFR); cell-therapy products that combine cell products with devices or drugs must comply with part 1271 and with the applicable cGMP regulations.

The regulations described in part 1271 are designed to prevent the introduction, transmission, and spread of communicable diseases. For example, compliance with cGTPs would require such precautions as cleaning of facilities and equipment, storage procedures designed to prevent product mix-ups, and controls over processing to prevent product contamination and impairment to function or integrity. cGTPs include, at a minimum, requirements for the appropriate collection, processing, labeling, storage, and distribution of cellular products to ensure maintenance of the product's function and integrity but do not require the rigorous environmental and manufacturing controls inherent in cGMPs.

In the final rule enacting establishment registration, the FDA defined products regulated solely under this section (lowest level of regulation) if they are (1) minimally manipulated; (2) intended for homologous use only (e.g., serves same basic function as cells being replaced); (3) not combined with a drug or a device, except for a sterilizing, preserving, or storage agent; and (4) either without a systemic effect and not dependent on the metabolic activity of living cells or have a systemic effect or are dependent on the metabolic activity of living cells for their primary function and are for autologous use or for allogeneic use in a first-degree or second-degree blood relative.[293] This includes most HSC transplantation. Products not meeting this description are still subject to these core requirements found in part 1271, but are also subject to more stringent requirements, including the requirement for premarketing approval (gained through submission of data from preclinical and clinical studies demonstrating safety and efficacy for the use being requested) and cGMP manufacturing requirements, as described in the regulatory approach for somatic cell therapy products.[294]

Chapter 61

Tissue Banking in the Hospital Setting

A. Bradley Eisenbrey • D. Michael Strong

INTRODUCTION

Tissue for transplantation belongs in the hospital blood bank. No other service in the hospital has the experience with the regulatory environment and compliance, Good Manufacturing Practices (GMPs), diverse storage requirements, inventory and record management, and tracking and tracing of human products. Like blood products, tissues have transmitted infectious diseases to recipients[1–10] and have required look-backs and recalls.[11] Application of the skills honed with blood components to "banking" tissue is a logical and conceptually simple expansion of services for the hospital blood bank.

Most hospital blood bankers were unaware of the volume and extent of human tissue use within their institutions until the Joint Commission on Healthcare Organization (JCAHO) published updated Standards in 2005, effective in July 2005.[12] The updated Standards require JCAHO-accredited institutions to name a single authority for oversight of tissue acquisition, storage, and tracking, and to create storage and tracking procedures and protocols consistent with the GMP standards followed in the transfusion medicine community. The new JCAHO Standards were a direct response to new federal regulations that brought United States Food and Drug Administration (FDA) oversight of nonmedical device human hematopoietic stem cell and tissue use in the United States and establishment of Good Tissue Practices (GTPs).[12,13]

Bone, tendon, skin, heart valves, corneas, sclera, fascia, and other tissues from deceased donors are transplanted every day in hospitals throughout the United States.[14–16] These tissues are recovered by registered eye and tissue banks, which screen the donors, perform disease-marker testing, process, package, and distribute the tissues to the physicians and dentists who implant the tissues. Tissues are recovered under aseptic conditions and undergo processing, which may vary from simple packaging to extensive computer-controlled milling, freezing, lyophilization, irradiation, or complicated washing processes. Some vendors report that their process produces sterile tissues.[15]

Most hospital blood banks have had little contact with these tissues other than informal arrangements for temporary storage of frozen tissue in a blood bank freezer or for holding a cornea in the blood bank refrigerator because of a delay in an operation. Although some hospitals are registered tissue banks and participate in the whole manufacturing process, "hospital tissue banking," for the purpose of this chapter, will refer to acting as a "consignee" or storage and distribution point for tissues within the hospital setting.

HOSPITAL TISSUE BANKING MODELS

Two models exist for handling tissues within the hospital setting. The most common model is the "decentralized" or "distributed" model, in which tissue is ordered, received, stored, and used within each of the separate hospital service areas. The decentralized model is exemplified by an ophthalmologist who places a direct order for a cornea from an eye bank, takes receipt of the cornea in the surgical suite, performs the transplant, and records the tissue information in the patient record. Similarly, an orthopedic surgeon may obtain a milled piece of lyophilized bone, or a vascular surgeon may obtain a frozen venous graft directly from a vendor and take delivery in the operating room. In each of these examples, the transplanting surgeon, and/or the surgical service, takes responsibility for ensuring the proper handling of the tissues from receipt to implantation. There may or may not be a log in which the receipt of the tissue at the hospital is recorded.

Alternatively, tissue "banking" in the hospital can be centralized in the department that runs the operating rooms, the hospital central supply, the pharmacy, or the blood bank. The knowledge, skills, and experience of hospital blood bankers make the blood bank the optimal choice.

The business of the hospital blood bank has been to provide patients with the appropriate blood products for their needs and to ensure that an adequate inventory of those blood products is maintained to prevent harmful delays in patient care. As technology advanced, the menu of blood products has expanded from the humble beginnings in whole blood kept in a refrigerator to a complex selection of packed red cells in the refrigerator, frozen plasma products in the freezers, and platelets maintained at room temperature. All of these are monitored. Add irradiation, leukocyte reduction, and screening for specific antibody or antigen negativity, and the inventory of most large hospital blood banks rivals other centralized services in complexity. The variety of monitored storage conditions resulted in the blood bank's becoming a useful intermediate storage place for human tissues foreign to most blood bankers. Bone, skin, vascular tissues, and other tissues such as corneas found their way onto the shelves of many blood banks, most often with informal agreements, if any.

Until 2005, the retrieval, processing, and distribution of bone, ocular, vascular, and connective tissue were virtually unregulated, with the exception of a few state laws and voluntary standards. Unless the tissues were substantially altered, federal regulations did not apply. It was routine in most hospitals for business transactions between the surgeon implanting the tissue and the vendor to occur without oversight by the institution in which the tissue was used.

Changes in federal regulations and voluntary standards of organizations like JCAHO and American Association of Blood Banks (AABB) have resulted in substantial changes in the way tissues are handled in hospitals.[13,17]

Ocular, vascular, and connective tissue and fresh and frozen bone have all been implicated in the transmission of bacterial, fungal, and viral diseases to transplant recipients, occasionally resulting in death. Retrieval of unused (stored) tissue after the identification of infectious cases has been complicated by the lack of formal tracking mechanisms. In some cases, the disposition of tissues was never known. The principle of being able to track a human tissue from the donor to the recipient (or backward) has, only recently, been applied to tissue banking, although the voluntary Standards of the American Association of Tissue Banks (AATB) and Eye Bank Association of America (EBAA) have incorporated the principle for years.[18,19] The tracking and traceability Standards of AATB and EBAA were enforceable only with their member tissue and eye banks. No enforcement existed for the end-user. AABB and JCAHO Standards require tracking and traceability to the patient.[12,20]

PROCESSES AND PROTOCOLS

Hospital tissue banking requires certain processes. A system must exist for a surgeon to select and order tissues appropriate for the types of surgery he or she performs and which meet the special anatomic and medical needs of the patient. The tissue must be ordered from the vendor (manufacturer). This requires establishment of purchasing and contractual arrangements. The tissue must be delivered to the hospital, and someone must take responsibility for acceptance of the tissue. The tissue may need to be stored before use, particularly if surgery is delayed or the tissue is found to be unsuitable for the particular patient. Informed consent for the use of allogeneic tissue must be obtained and documented. The tissue must be properly handled in the operating room, including careful final inspection to verify its type, suitability, and condition. The tissue must be properly reconstituted, if applicable. The use of the tissue must be appropriately documented in the patient's permanent medical record. The vendor must be notified of the disposition of the tissue to allow tracking in the event of a recall, usually by return of preaddressed reporting forms. Finally, a mechanism must exist for recognition and reporting of complications due to the tissue implanted.

A decentralized system for tissue handling places responsibility for ordering, receipt, storage, and tracking in the hands of the surgeon or service in which the tissue is used. This has been efficient for the surgeon because it eliminates administrative layers and allows ordering tissue on a highly individualized basis, when needed. If the salesperson for the tissue manufacturer is responsible, the support staff for the surgeon is appropriately trained to ensure proper storage and handling of the tissue, and the surgeon or operating room staff ensures proper documentation of the use of the tissue, including reporting to the vendor, this process can be effective. Tracking and traceability can be augmented in this system by the use of a tissue log in the surgical suite (tissue-accession register or record). In many cases, the salesperson for the vendor delivers the tissue and takes responsibility for ensuring proper handling and storage, up to and including the operating room.

JCAHO recognized the lack of standardization of tissue handling in hospitals and the difficulties that had been reported for tracking tissues that had been delivered to hospitals and established new Standards for member hospitals, beginning July 1, 2005.[12] The new JCAHO Standards incorporated many of the voluntary standards of the AATB, EBAA, and AABB (formerly American Association of Blood Banks). A Standard "unique" to JCAHO is a single individual responsible for the oversight of tissue in the hospital. JCAHO has created a responsible party for all tissue delivered to each member hospital.[12]

The JCAHO Standards do not preclude decentralized tissue handling in a hospital, but do modify the process and require a single person to keep track of each of the individual practices within the institution. Creation of a standardized protocol with uniform documentation will simplify the work of the tissue monitor.

Tissue banking at the author's organization, William Beaumont Hospital, Royal Oak, Michigan, evolved over a decade from a casual arrangement of holding tissues in the Blood Bank refrigerator or freezer to a formal process mandated by the hospital Blood Transfusion and Tissue Committee. Initial resistance to an ordered and centralized process is contrasted, today, with ready acceptance, high praise for the quality of the services provided, and swift rejection of a proposal to move responsibility to the operating room service.

The transition from casual to fully controlled was facilitated by four critical components: (1) an existing blood bank computer system that was readily adapted to manage tissue products like blood products, (2) an existing working relationship with the operating room team for specialized products that were already being stored in the blood bank, (3) a team of outstanding medical technologists with excellent supervision, and (4) a dedicated senior medical technologist (Hospital Tissue Coordinator) who had a good working knowledge of the tissue requirements and was able to communicate effectively with surgeons as problems arose. The process does not happen overnight, is unlikely to work as a "turn-key" operation, and continues to evolve as the product mix and size of the inventory changes.

The tissue banking process used at William Beaumont Hospital (WBH), Royal Oak, is a logical extension of the existing processes used for receipt, acceptance, storage, inventory, issuing, and tracking of blood products. The process is built with consideration of the published Standards of the AABB for handling and storage of tissues. Although most tissue products were not regulated by the federal government when the procedures and protocols used at WBH were established, all the tissue products were treated in the same manner as blood products. Experience as a registered blood establishment and a well-established quality assurance program helped in developing the procedures and processes for handling fresh, frozen, and lyophilized tissues.

Product Selection

Tissues for transplantation can be recovered from deceased donors (skin, cornea, sclera, cartilage), frozen (bones, vessels, valves) after initial aseptic recovery and processing, or further processed (bone, connective tissue) through lyophilization, patented washing/sterilization methods (Allowash; LifeNet, Virginia Beach, Va.; Bio-cleanse; Bio-cleanse Technologies, Bellingham, Wash.). Bone, in particular, can be milled and

tooled to obtain unique shapes and structural characteristics unavailable in the native tissue.[15,21]

Product selection is driven by the transplanting surgeon. The surgeon contacts the Hospital Tissue Coordinator (HTC) with a request for a particular tissue product by using the Request Form (Fig. 61–1). If the product is from a vendor that has already been evaluated and qualified, the product is ordered and placed into the inventory on receipt. If a similar product is already in the inventory or is available from a qualified vendor, the HTC will contact the surgeon with that information and will attempt to persuade the surgeon to accept the existing product as a substitute. If the vendor has not been qualified, the surgeon is notified that the request cannot be filled as requested until the vendor qualification is complete and a site visit is arranged. Tissues from nonqualified vendors are not allowed into the hospital. This is enforced through the inability of the vendor to bill for any products not authorized by the HTC.

A key component of a successful centralized hospital tissue bank is the support of the hospital Purchasing Department. Vendors are not allowed to deliver tissues to the operating rooms, and payments are not authorized for tissues that are not ordered by the HTC. These practices keep unauthorized tissues from being brought into the hospital and ensure compliance with tracking requirements.

Vendor Qualification

Vendor qualification includes documentation of certification by AATB, all necessary licensure (i.e., Florida and New York) and/or registrations, and evaluation of the processes used in donor acceptance, prevention of cross-contamination, tissue processing, storage, tracking, quality assurance, and staff training and competency evaluation. Vendor qualification has required site visits by the Medical Director or Associate Medical Director, HTC and/or Blood Bank Quality Assurance Officer. A template can be used for evaluation to ensure completeness. The supporting documents are requested before the site visit.

Inventory Control

Inventory control is dynamic and similar to management of the blood product inventory. The turnover rate of each product is carefully monitored so that enough tissue is maintained in the inventory to prevent having to postpone surgery. If a particular tissue is nearing outdate, the HTC works closely with surgeons and operating room staff so that the tissue will not be discarded. The most significant problem with tissue is the unusual special-order bone or cardiovascular tissue that is obtained (usually frozen) for a particular patient. Outdates happen and can be significant financial events as well as an unfortunate waste of donated cadaveric tissue.

Inventory is communicated to the surgeons through continuously updated catalogs of available tissues. The catalogs are kept in the operating room cores. Telephone calls are placed to the surgeons' offices when special-order tissue arrives. The inventory is available to all of the blood bank staff through the blood bank computer system as a look-up function so that availability can be confirmed. A copy of the catalog is kept in the blood bank.

In 2005, no uniform labeling or nomenclature exists for tissue products. As a result, unique product codes are generated by the HTC to allow tracking of the inventory. In some cases, the product codes of the manufacturer can be directly incorporated; however, unique identifiers are not standardized across vendors, so some creativity is necessary until standardization develops. The result is an unusual mixture of product codes that may defy logic in the naming because of the complexity of the inventory and the number of different product codes required. A movement to adopt ISBT code 128 labeling standards by European Tissue Bank organizations would greatly simplify inventory management and tracking.[22]

Because of the lack of a uniform national labeling standard, each product brought into the inventory is given a unique tracking number generated by the blood bank. These can be referenced to the individual product for recalls. The unique tracking number can be referenced from the patient back to the product and the vendor in the event of an adverse outcome from the transplant.

The challenges of inventory control include the large number of highly specialized, milled bone products, many designed solely for a single surgical-instrument manufacturer's tools. This boutique approach to inventory can result in expensive duplication and waste if a surgical tool goes out of fashion. Although tissue invoices will not be paid if the tissue was not ordered by the blood bank HTC, and all tissue must be delivered to the blood bank to be accessioned, vendors and salespeople continue to approach the surgeons directly and enter the operating room to pitch their wares, occasionally under the guise of demonstrating new products.

ECONOMIC CONSIDERATIONS

Tissue products are expensive. The vendor charges for tissues range from approximately $360 for a 30-mL volume of cancellous chips to $2900 for complex milled products (femoral trapezoid ring) and $3700 for special-order frozen bone products (whole femur) (W. Frizzo, MT [ASCP], personal communication). Cryopreserved heart valves can exceed $7500 (D. Michael Strong, PhD, personal communication). A centralized inventory and bank in the hospital allows close tracking of the inventory to ensure that "short-dated" products get used rather than being discarded. Improper handling resulting in wastage can be identified and corrective actions put in place. For example, a circulating nurse, who opens multiple tissue packages in the operating room instead of waiting for the surgeon to select the appropriate product, can be educated on the expense and the impact of wasting the products.

An additional benefit of a centralized program is the ability to negotiate better pricing from the vendors because of better knowledge of the competing products and the ability to do volume purchasing and standing orders. The cost of "drop-shipping" or hand delivery of individual tissue products is always greater than the scheduled purchasing arrangement. Even products with short "shelf life" can be scheduled into an inventory with careful management.

Another benefit of centralized purchasing and inventory is the ability to encourage competition between vendors for quality improvements, improvements in supply, and customer service. The direct sales model, preferred by the vendors because of the loyalty factor created by the interaction of the salesperson and the surgeon, restricts any cost comparisons.

ACCESSIONING TISSUES

Accessioning tissues follows the template of the receipt of blood products. The packaging is inspected for damage,

labels are checked, and the temperature of the shipped product is evaluated to ensure that the product stayed within the acceptable range determined by the manufacturer. If these are in order, the tissue is accessioned into the inventory and assigned unique product and tracking numbers for the computer system. The process is facilitated by vendors that barcode products. Barcode labels are printed with the unique product identification/tracking numbers for the products that are not barcoded (or when barcoding is unusable) by the manufacturer. The accessioning process includes the storage location to ease finding the tissue when it is requested.

Storage and Handling

Storage and handling requirements are set by the vendor (manufacturer) for each tissue product. AABB and JCAHO Standards require continuous temperature monitoring and documentation of the temperatures of refrigerators and freezers.[12,20] In addition, storage equipment must have functional alarms and emergency backup. AABB Standards require monitoring and recording of the room temperature.[20] The importance of this is not immediately apparent without recognition of the number of products that are stored at "room temperature." Most manufacturers are becoming more explicit in the definition of room temperature.

Packaging

Packaging is not generally an issue for the end user or consignee unless the product is damaged in handling. For those institutions that store autologous tissues, however, packaging becomes an important step in the manufacturing process. The ideal packaging is built of sealable clear plastic pharmaceutical grade bags that will remain flexible at freezer temperatures and will tolerate gamma or x-ray irradiation. Clear packaging allows inspection of the contents without opening the package and immediate recognition that the correct tissue product has been selected (e.g., Rollprint Packaging Products, Inc., Addison, Ill., and Kimberly-Clark, Roswell, Ga.). Opaque overwraps may ease handling within the operating room by allowing traditional opening procedures for the nurse assisting the surgeon, but the contents are collected aseptically and should not be considered sterile unless sterility is proven.

Barcoding

Barcodes are not standardized between vendors. When barcoding is present on the tissue product packaging, the information encoded can vary dramatically from vendor to vendor, ranging from simple product identification to embedded coding allowing traceability to the individual donor. In many cases, the coded information is not sufficient to allow an individual tissue product to be uniquely identified. In these circumstances, the addition of a locally produced barcode label may improve inventory control, tracking, and the ability to trace from the patient back to a specific tissue-product vendor when complications occur.

Issuing

Issuing tissues requires a request form for each tissue (see Fig. 61–1). The request forms are patient specific, and the tissues are issued to a specific patient rather than to a surgeon or operating room. The unique identifier is used to link the specific tissue product permanently to the specific patient. When the tissue product is issued, it is accompanied by a multiple-part form for tracking similar to the "transfusion tag" used in most blood banks (Fig. 61–2). The first page of the multipart form is placed in the patient record, and the duplicate page is returned to the blood bank. Reporting forms (frequently a postcard format) for the manufacturer can be returned directly by the surgeon or the HTC.

Tracking

Tracking is performed on multiple levels. Because all tissue comes to the blood bank in the centralized model, the location of all unused tissue is known, virtually immediately. In the author's experience, a major vendor recall was completed in less than 15 minutes, with all tissues accounted for. Because tissue is issued for a specific patient, the assurance that it is used for the specified patient is very high (chart record audits have been consistent for the final disposition) but will be improved when electronic records allow a direct link between the barcoded product and a specific patient's record. Untoward events can be linked to the specific tissue because surgical complications (e.g., wound infections) reported to the hospital epidemiologists are crosschecked against the daily tissue-use listing.

Traceability

Traceability is maintained by the direct one-to-one link of a patient to a specific tissue issued from the blood bank, which is linked to the unique identifiers of the tissue and for the manufacturer. Some manufacturers embed the donor information that can be recovered to allow tracing back from the recipient to the donor. The blood bank computer database is archived on a continuous basis with routine backups and results in a stable platform for future look-backs, if needed. Appropriately completed, vendor-supplied transplant-report forms can also improve traceability by documenting the link between the recipient and the donor.

Autologous Tissues

Calvaria (skull bone flaps),[23,24] bone,[25,26] skin,[27–29] and parathyroids[30,31] are frequently stored for various amounts of time for reimplantation in the original anatomic position (skull bone flap) or new location (iliac crest bone for spinal fusion, skin autografts for burn or plastic surgery, limb site for parathyroid reimplantation). The role of the hospital tissue bank can range from processing the tissue for long-term storage (see Packaging) to holding a tissue in culture media overnight. In most cases of autologous tissue transplants in the hospital setting, the tissue is removed, minimally manipulated, and reimplanted during the same surgical procedure. Careful records must be kept because autologous tissue can be forgotten by the surgeon and never used, thus becoming the blood bank's problem. Some limits must be placed on length of storage to avoid this situation.

Stem Cells and Reproductive Tissues

Stem cells and reproductive tissues are beyond the scope of this chapter. Stem cell and reproductive tissue collection, processing, storage, handling, and transplantation are regulated under 21CFR1271.[13] Stem cell laboratories and transplant centers are

TRANSFER OF TISSUES BETWEEN INSTITUTIONS

Current regulations consider hospitals and surgical centers as "consignees" or end users for tissues for transplantation.[13] If tissue for transplantation is stored at a hospital but transferred to another hospital for use, the hospital storing the tissue must meet GTP requirements and may be considered a vendor if the practice is routine. In May 2006, the Health Resources and Services Administration (HRSA) revised the definition of "organ" to include blood vessels (usually segments of iliac arteries and veins) recovered from an organ donor during the same recovery procedure such as organ(s) and intended for use in organ transplantation. This excluded blood vessels intended for use in organ transplantation from the definition of human cells, tissues, and cellular and tissue-based products (HCT/Ps).

Because of this revision, blood vessels labeled and intended solely for use in organ transplantation became subject to HRSA requirements in 42 CFR part 121 and any enforceable organ procurement and transplantation network (OPTN) policies established under 42 CFR part 121.[34]

ORGANS AND THE HOSPITAL TISSUE BANK

The solid organ (renal, heart, lung, liver, pancreas, small bowel) transplant community has always understood the critical nature of ABO compatibility in transplant. Untoward events involving unintended ABO-incompatible transplants of organs resulted in revisions to the Standards of the United Network for Organ Sharing in 2005 (Standard 3.1.4.2; UNOS, Richmond, Va.). Many transplant centers changed internal procedures before the revision of the Standards to confirm the ABO group of the donor and recipient and to improve the documentation of the checks during the organ acceptance and transplant process.

Although time is critical and delays do result in poorer graft and recipient outcomes, ABO-incompatibility may be fatal and certainly can result in immediate graft loss. Accessioning solid organs through the hospital blood bank, confirming the ABO of the recipient (from review of repeated testing of blood group typing), and confirming the ABO of the donor organ by using a sample tube included with the organ gives

the surgeon and transplant team a final opportunity to check for ABO-compatibility and to document the acceptance of the organ for transplant. The greater the sensitivity of the organ to cold ischemia time, the more urgent the process. However, assumptions about prior testing and the inherent sense of urgency have contributed to fatal mistakes.[33]

Organs can be triaged in the hospital blood bank with the same efficiency that is present when handling a trauma or massive transfusion case. Well-defined procedures, carefully constructed tracking forms, and clear documentation facilitate the process and result in minimal delays. The author has seen the system work when two kidneys from deceased donors were accepted for two patients on the hospital transplant service within a couple of hours, and the second kidney arrived first. The blood bank check of the records stopped a fairly rapid process in which the first transplant team assumed that the kidney that was sent by the Organ Procurement Organization was for their patient and began prepping the operating room and preparing the patient. The chain of assumptions was broken, and the second transplant team was called in to proceed with the appropriate organ and recipient. Admittedly, this is highly unusual, and even less likely for other organs, but it demonstrated that the system worked.

CONCLUSIONS

The use of tissue will continue to increase until cultured or synthetic replacements are found for these highly successful, but potentially dangerous, transplants. Changes in federal regulations and JCAHO Standards have resulted in increased scrutiny and controls on the handling of these human products. The transfusion medicine community, particularly blood bankers, has had more experience than any other hospital organization with operating in the GMP environment and dealing with federal and state regulators and voluntary accreditation organizations. Tissues (and organs) are amenable to the processes, procedures, and protocols used by the hospital blood bank to order, accession, store, track, issue, and trace blood products.

of platelets, 321–322, 385t, 388, 555
Umbilical cord blood
advantages and disadvantages of, 539
banking of, 825–827
characteristics of, 827–829, 828t
HLA-matched, 823
Institute of Medicine report on, 826–827
multiple units, transplantation into single recipient, 824
multipotent adult progenitor cells, characteristics of, 828t, 829
progenitor cells
cryopreservation of, 825–826
endothelial, characteristics of, 827, 828t
hematopoietic, characteristics of, 827, 828t
RBCs, antigen expression, 56
Umbilical cord blood (*Continued*)
single unit, ex vivo expansion of, 824–825
stem cells, 791
characteristics of, 827, 828t
cryopreservation of, 825–826
enhanced homing of, 825
mesenchymal, characteristics of, 827–829, 828t
transplantation of, 539–540, 540t
in adults, 823–824
advances in (future directions for), 824–825
conditioning regimens for, 824
historical perspective on, 783, 823
regulation of, 783
storage of, legal considerations with, 247
unrestricted somatic stem cells, characteristics of, 828t, 829
United Network for Organ Sharing, 858
Universal donor, 74
University HealthSystem Consortium, guidelines for albumin usage, 278, 281–282, 282t
Unnamed antigen, 56t, 108
Uremia
coagulopathy in, 485–486, 486t
cryoprecipitate for, 270, 271, 273–274
hemostatic therapy in, 485–486, 486t
in pediatric patients, management of, 519, 519t
Uterine artery embolization, for postpartum hemorrhage, 497–498
Uterine rupture, 497

V
Vaccination(s), in blood donor screening, 164t, 168
Vaccinia, vaccination against, and blood donor deferral, 168
Vaccinia Ig Intravenous (Human), 299
Valproate, and risk for obstetrical hemorrhage, 496, 497t
Vancomycin, and platelet refractoriness, 553
Variable nucleotide tandem repeat (VNTR), in microchimerism analysis, 715
Variable region, 17, 57
Varicella-zoster virus (VZV)
infection
hyper-Ig for, 299
post-transplant, in stem cell recipient, 795
and paroxysmal cold hemoglobinuria, 557t, 565
Vasculitis
immune complex-mediated, 564
systemic
classification of, 751, 751t
therapeutic plasma exchange (TPE) for, 729t, 750t, 751
Vasovagal reaction(s), in blood donors, 172–173, 174t
VDJ rearrangement, 17, 17f, 25
Vel, antibodies, clinical significance of, 59t
Vel antigen, 56t, 108
Venereal Disease Research Laboratory (VDRL) test, 658
Venipuncture
local tissue injury in, 173, 174t
site for, disinfection of, 316
Very late activation antigen, VLA-2. *See* Integrin(s), $\alpha_2\beta_1$
VIGIV, 299
Viral disease(s). *See also* Pathogen reduction; *specific virus*
immune response to, transfusion and, 705–706
and paroxysmal cold hemoglobinuria, 557t, 565
post-transplant, in stem cell recipient, 795
transfusion-transmitted, 316
estimated risk of, 436t
prevention of, 167–169, 383–407
residual risk for, 383
window period, 167
Virus(es). *See also specific virus*
in fresh-frozen plasma (FFP), 265–266
immune defense against, microRNAs in, 16
inactivation, 612–613
methods for, 468
in solvent/detergent-treated plasma, 260, 265–266, 384, 391–393
Visual swirl, for detection of platelet bacterial contamination, 317, 644t, 647
Vitamin K, 261–262
Vitronectin, 38
and complement regulation, 34–35, 34t
platelet membrane glycoprotein and, 112, 113t
VivoStat[25], 272
Volume expanders, 251
Volume expansion, after cardiac surgery, albumin for, 282t, 284
von Willebrand disease, 474–477
adjunctive treatment of, 477
bleeding in, 474–475
classification of, 475
cryoprecipitate for, 270, 271, 273
diagnosis of, 476
epidemiology of, 474
laboratory findings in, 476, 476t
pathophysiology of, 474–475
in pediatric patients, management of, 519, 519t
platelet-type, 355–356
pseudo-, 355–356
subtypes of, 355–356
treatment of, 353, 355–356, 476–477
type 1, 475, 476t
type 2 (2A, 2B, 2M, 2N), 475–476, 476t
type 3, 475, 476t
von Willebrand factor, 309, 355–356
in cryoprecipitated AHF, 197, 270, 271, 272
deficiency of, 475
exogenous replacement of, 477
functions of, 474–475
platelet membrane glycoprotein and, 112, 113t
structure of, 474–475
in thrombotic thrombocytopenic purpura (TTP), 263
ultralarge, metalloproteinase cleavage of, 747–748

W
WAHA. *See* Autoimmune hemolytic anemia (AIHA), warm
Waldenström's macroglobulinemia
and cold agglutinin disease, 563, 565
and cryoglobulinemia, 564
stem cell/marrow transplantation for, 804–805, 805t
Walker v. Humana Medical Corporation, 245
Warfarin
anticoagulation with
physiology of, 261–262
reversal of, 262
coagulopathy caused by, 489–490
fresh-frozen plasma (FFP) for, 261–262
reversal of, 490, 490t
in pediatric patients, management of, 519, 519t
Warranty, implied, 245
as legal consideration, 240
Washing, of blood components, procedure for, 198
Water bath disinfection, 648
Water channel proteins, 102–103
Wegener granulomatosis, 751
Western blot, for HIV testing, 219, 606
West Nile virus, 663–664
detection of, 10
geographic distribution of, 663
infection
clinical features of, 664
serology of, 663–664, 664f
transplant-associated, 664
nucleic acid amplification testing (NAT) for, 214, 214t
testing for, 213, 216, 664
transfusion-transmitted, 383
estimated risk of, 436t
legal considerations in, 242
prevention of, 170
virology of, 663
Whites
Dombrock blood group system in, 102, 102t
Duffy blood group system in, 90, 90t
incidence of ABO blood groups in, 70, 71t
incidence of antigen negativity in, 61, 61t
Kell antigens in, 88, 89t
Kidd blood group system in, 91, 91t
Lewis blood group phenotypes in, 74, 74t
MNS blood group system in, 96, 97t
P blood group system phenotypes in, 76, 77t
Whole blood
autologous
with erythropoietin administration, indications for, 425
indications for, 425
collection procedures for, 170, 187–190, 250
donors, requirements for, 187

Whole blood (*Continued*)
expiration of, 191t
indications for, 250t, 251
irradiated, 401–402, 402t
expiration of, 191t
preparation of, 198–199
storage of, 191t
transport of, 191t
number of units collected annually, 250
processing of, for component preparation, 190–194
reconstituted, indications for, 413
separation methods for, 190
specific gravity of, 187
storage of, 191t, 647
transfusion of, indications for, 190
transport of, 191t, 200
unit of, volume of, 250
WBC content of, 401, 401t
weight calculations for, 187
Window period
in CMV infection, 627
in HIV infection, 214–215, 606
of viral disease, 167, 214–215, 236, 327
Wiskott-Aldrich syndrome (WAS), 25
Women, multiparous
deferral of, 697
plasma from, 697
World Health Assembly (WHA), resolution WHA58.13, on blood services in economically restricted and developing countries, 573–574
World Health Organization (WHO). *See also* IUIS/WHO
and blood services in economically restricted and developing countries, 571–572, 578–579
guidelines for plasma collection, 278, 290
World War II, transfusion medicine in, 8–9, 9f
Wound healing
fibronectin and, 274–275
postoperative, transfusion and, 705
Wright v. Fred Hutchinson Cancer Research Center, 243–244

X
Xg blood group system, 54f, 56t, 100–101
evolution of, 101
expression of, 101
functions of, 56t, 101
gene for, 56t, 101
historical perspective on, 100
protein, 101
Xg^a antigen, 100–101
antibodies, 101
characteristics of, 58t
clinical significance of, 59t
and CD99, phenotypic relationship of, 101, 101t
Xigris, 356
XK gene, 88
XS gene, 98–99

Y
Yersinia enterocolitica, contamination of blood components, 640, 641t, 642, 647
Yt blood group system, 54f, 56t
antibodies, 100
clinical significance of, 59t
evolution of, 100
functions of, 56t, 100
gene for, 56t, 100
historical perspective on, 100
Yt^a antigen, 56t, 100
antibodies, characteristics of, 58t
Yt^b antigen, 56t, 100
Yus phenotype, 104–105
